Dihydropteroate synthetase (DHPS) is a validated target enzyme of sulfadoxin. This could be shown for sulfadoxin-resistant *P. falciparum* isolates. DHPS from resistant and sensitive strains differ in their amino acid sequences. Indeed, there is a correlation between point mutations in the bifunctional DHPS and sulfadoxin resistance. Interestingly, DHPS of *P. falciparum* is a bifunctional enzyme which includes the dihydro-6-hydroxymethylpterin pyrophosphokinase at the amino terminus.

Ethopabate

Synonyms

Methyl 4-acetamido-2-ethoxybenzoate, Ethyl pabate, in combination with amprolium: Amprol Plus.

Clinical Relevance

Ethopabate is only a narrow anticoccidial spectrum drug against *Eimeria acervulina*. It has no or only slight activity against *E. maxima*, *E. necatrix*, *E. tenella* or *E. brunetti*. Today, ethopabate is applied only in combination with amprolium and sulfonamide (Table 1).

Molecular Interactions

Ethopabate is a 2-substituted PABA derivative (=4-acetamido-2-ethoxybenzoic acid methylester) and functions as a prodrug. Its activity becomes potentiated by pyrimethamine and antagonised by the simultaneous administration of PABA. Thus, the mode of action of ethopabate is similar to that of sulfonamides or sulfones (Fig. 1).

Nicarbazine

Synonyms

4,4'-dinitrocarbanilide, Altek, Elancocin, Nicarb, Nicoxin, Nicrazin.

Clinical Relevance

Nicarbazine is used against coccidiosis in poultry. It has a coccidiostatic action by impairing the ► [oocyst](#) formation of the late life cycle stages. The numbers of oocysts are only reduced so that a latent infection up to the last life cycle stages is always detectable. Thus, nicarbazine-treated animals can develop immunity against coccidia.

Molecular Interactions

The activity is directed against schizonts of the second generation of *Eimeria* spp. An inhibition of folate biosynthesis is proposed (Fig. 1).

2,4-Diaminopyrimidines

Important Compounds

Pyrimethamine, Trimethoprim, Diaveridine, Ormetoprim, Epiroprim, Pirithrexim.

Synonyms

Pyrimethamine: Daraprim, RP4753, Chloridin, Darapram, Malocide, Tindurin; in: Fansidar, Suldox, Malocide, Maloprim, Metakelfin.

Trimethoprim: 2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine, Monotrim, Proloprim, Syraprim, Tiempe, Trimanyl, Trimopan, Trimpex, Wellcoprim; in: Borgal, Cosumix, Leotrox, Protox, Tribissen, Trafigal, Vetoprim, Bactrim, Eusaprim, Septrin, Sultrim.

Diaveridine in: Darvisul, Rofenon.

Ormetoprim in: Rofenaid-40, Ektecín.

Epiroprim: none.

Pirithrexim: none.

Clinical Relevance

2,4-diaminopyrimidines (pyrimethamine, trimethoprim) are active against a wide variety of human and veterinary pathogens. Thus, they possess a broad antibacterial spectrum. Antiprotozoal active 2,4-diaminopyrimidines used in human medicine are pyrimethamine and trimethoprim. They are used for ► [prophylaxis](#) in ► [malaria](#), but the onset of antimalarial activity is very slow. They have no general effect on gamonts and no effect on ► [hypnozoites](#) of *P. vivax*.

(► **Hem(oglobin) Interaction**/Fig. 2). Because of the frequently occurring resistance against pyrimethamine they are applied in combinations with sulfonamides (sulfadoxin) (Fansidar). In general, combinations of pyrimethamine and trimethoprim with sulfa drugs are of great medical importance for treatment of toxoplasmosis (Table 2), ► *Isospora belli* infections and *Cyclospora cayetanensis* infections in ► **AIDS** patients. Thus, combinations of pyrimethamine with sulfonamides such as sulfadiazine, sulfadimidine or sulfadoxin belong to the standard treatment for human toxoplasmosis. However, these combinations are restricted for the treatment of ► **prenatal toxoplasmosis** in the time after the 20th week. In addition, a pyrimethamine-sulfonamide combination is the drug of choice for postnatal infections with *Toxoplasma gondii* in children and in AIDS patients. For tolerability reasons and especially for prophylactic treatment, a combination of trimethoprim and sulfamethoxazole sometimes in a combination with clindamycin is recommended. There are only anecdotal reports of treatment of ► **microsporidiosis** in AIDS with trimethoprim/sulfamethoxazole.

2,4-diaminopyrimidines used in veterinary medicine are pyrimethamine, ormetoprim, epiroprim, pirithrexim and diaveridine. They are routinely used against coccidiosis in combinations such as ormetoprim/sulfadimethoxine or sulfaquinoxaline/amprolium/ethopabate/pyrimethamine (=Supracox). A combination of clarithromycin and pyrimethamine has been shown to be effective against toxoplasmosis in animals, but is not well tolerated. In addition, a pyrimethamine/sulfamethazine-combination is reported to be effective against *T. gondii* in sheep and goats (Table 2). Trimethoprim or pyrimethamine as single drugs or together in combination show curative effects in *Neospora caninum* infections, when motor nerve disturbances have already occurred (Table 2). Epiroprim is a relatively new 2,4-diaminopyrimidine for the treatment of toxoplasmosis. It possesses an in vitro activity against *T. gondii*. There are promising results in animal experiments with a dapsona/epioproprim-combination. Pirithrexim, another 2,4-diaminopyrimidine, and pyrimethamine have

been shown to be active against *N. caninum* ► **tachyzoites** in cell cultures.

Besides the antibacterial and the antiprotozoal activities 2,4-diaminopyrimidines are useful as anticancer drugs and in therapy of rheumatic diseases.

Molecular Interactions

Pyrimethamin is a selective inhibitor of the dihydrofolate dehydrogenase (DHFR) of exoerythrocytic schizonts (in the liver) and erythrocytic schizonts of ► **malarial parasites** (► **Hem(oglobin) Interaction**/Fig. 2) and other sporozoa such as *Toxoplasma* and *Eimeria*. Schizonts become damaged by pyrimethamine only during ► **nuclear division**. There is no effect on the parasitic ring forms of *P. falciparum*. Pyrimethamine has an additional activity against oocysts in mosquito gut. Besides pyrimethamine the parasitic DHFR is also inhibited by the other 2,4-diaminopyrimidines trimethoprim, epiroprim, diaveridine and ormethoprim (Fig. 1). It has been well established for a long time that there are synergistic effects between the 2,4-diaminopyrimidines as DHFR-inhibitors and sulfonamides as inhibitors of dihydropteroate synthetase, when given in combination (Fig. 1).

Resistance

Most knowledge about the resistance mechanism against pyrimethamine at the molecular level comes from experiments with plasmodia. A modification of the target receptor DHFR in the folic acid pathway in resistant strains very likely results in a decrease of DHFR sensitivity to inhibition. There are several reports that the molecular basis of pyrimethamine resistance in naturally resistant isolates of *P. falciparum* are single point mutations (e.g., Ser-108 ⇒) in the DHFR active site (Fig. 3). There is a good correlation between mutations with natural pyrimethamine resistance in a variety of geographically distant isolates. In addition, the two ancillary mutations Asn-51 ⇒ Ile-51 and Cys-59 ⇒ Arg-59 are associated with increased pyrimethamine resistance in the presence of Asn-108.

Another mechanism of pyrimethamine resistance in *P. falciparum* has been proposed.

DNA-Synthesis-Affecting Drugs IV: Interference with Cofactor Synthesis,

Fig. 3 Schematic model of the point mutations in the active site of dihydrofolate reductase of *Plasmodium falciparum* (Gutteridge (1993) In: Cox FEG (ed) Modern Parasitology, 2nd edition, Blackwell Science, pp. 219–242)

Thereby, an overproduction of DHFR achieved either by gene duplication or by other mechanisms resulting in increased expression is discussed as being responsible for resistance on the molecular level.

Chlorproguanil

Synonyms

Chlorguanil, 1-(3,4-dichlorophenyl)-5-isopropylbiguanide, M5943, hydrochloride: Lapudrine.

Clinical Relevance

Chlorproguanil serves as a causal prophylactic, but not as a therapeutic drug for malaria. Its effectiveness is not different from proguanil.

Molecular Interactions

The target of chlorproguanil is the dihydrofolate reductase of the parasitic stages. It has an influence on sporozoites and the exoerythrocytic stages of all four *Plasmodium* spp. (► [Haem \(oglobin\) Interaction](#)/Fig. 2). The onset of the effect on erythrocytic stages is very slow. The activity is directed against exoerythrocytic schizonts, erythrocytic schizonts and oocysts in mosquito gut (► [Haem\(oglobin\) Interaction](#)/Fig. 2).

Resistance

There is cross-resistance between chlorproguanil and pyrimethamine indicating the same mode of action by inhibition of the DHFR (Figs. 1 and 3).

Proguanil

Synonyms

Chlorguanide, 1-(p-chlorophenyl)-5-isopropylbiguanide, Chloroguanide, M4888, RP3359, SN12837, Diguanil, Drinupal, Guanatol, Paludrine, Palusil, Tirian; Combination: Proguanil, Atovaquone (Malarone®).

Clinical Relevance

Proguanil was explored in 1945. It was developed for prophylaxis against malaria, but the prophylactic activity is not complete. It leads to a damage of exoerythrocytic schizonts. It has no effect on the hypnozoites in the liver. The fixed combination of proguanil and atovaquone (Malarone®) is used for prophylaxis and therapy (including emergency self-medication) of uncomplicated *P. falciparum* infections for adult patients as well as for children. The combination shows good efficacy and tolerability (► [Hem\(oglobin\) Interaction](#)/Table 1). For atovaquone see DNA-Affecting Drugs V.

Molecular Interactions

Proguanil belongs chemically to the biguanids. It is a prodrug, which is converted to cycloguanil, a cyclic triazine with antimalarial activity. The activity is directed against exoerythrocytic schizonts in the liver, erythrocytic schizonts and oocysts in mosquito gut (► [Hemoglobin Interaction](#)/Fig. 2). The mode of action is the selective inhibition of the DHFR of malarial parasites (Figs. 1 and 3).

Resistance

There are specific DHFR point mutations responsible for resistance to cycloguanil which could be shown in a variety of independent *P. falciparum* clones and isolates. From examination of the point mutations of DHFR it becomes clear that there is a different molecular basis for resistance to cycloguanil and pyrimethamine, depending on the positions of the mutations and on the residues involved. Point mutations result in an inhibition of pyrimethamine binding at the active site of the reductase (Fig. 3). But there are presumably different effects of the DHFR point mutations on pyrimethamine and cycloguanil, since proguanil is sometimes effective against pyrimethamine-resistant *P. falciparum*, indicating that there may be different binding sites for both drugs. In other cases there is cross-resistance between proguanil and pyrimethamine observable.

DNA-Synthesis-Affecting Drugs V: Interference with Dihydroorotate Dehydrogenase

Structures

Figure 1.

Hydroxyquinolines

Important Compounds

Amquinat, Buquinolat, Decoquinat, Methylbenzoquat.

Synonyms

Amquinat: none.

Buquinolat: 4-Hydroxy-6,7-diisobutoxy-3-quinolinecarboxylic acid ethyl ester, Ethyl 6,7-diisobutoxy-4-hydroxyquinoline-3-carboxylate, Bonaid.

Decoquinat: Ethyl 6-(n-decyloxy)-7-ethoxy-4-hydroxyquinoline-3-carboxylate, M&B15497, Deccox.

Clinical Relevance

4-hydroxyquinolines have antiparasitic activities against *Toxoplasma* spp., ► *Pneumocystis carinii*, and *Cryptosporidium parvum*, and they furthermore possess anticoccidial, antimalarial, and antitheilerial activity. Decoquinat is active against *T. gondii* in cats (► [DNA-Synthesis-Affecting Drugs IV](#)/Table 2) and is still used in shuttle programs against coccidiosis. For such shuttle programs it is of great advantage when the single components exert synergistic activity. This is the case for methylbenzoquat and meticlorpindol (clopidol) (► [Energy-Metabolism-Disturbing Drugs](#)), which are used in combination in such shuttle (rotation) programs. However, as single compounds they have only limited success as anticoccidials.

Hydroxynaphthoquinones

Important Compounds

Parvaquone, Buparvaquone, Atovaquone, Menocone; Combination: Atovaquone/Proguanil (Malarone®).

Synonyms

Buparvaquone: Butalex; Menocone: Menocon; Parvaquone: Clexon.

Clinical Relevance

The potential of this class of 2-hydroxynaphthoquinones was realized over 50 years ago. Parvaquone and buparvaquone have antibabesial and antitheilerial activity (*Theileria parva* in cattle). Against ► [theileriosis](#) parvaquone acts against the schizonts in lymphoid cells, thereby, selectively destroying infected

**Decoquinate****Buquinolate****Methylbenzoquate****Paravaquone****Buparvaquone****Atovaquone****Menoctone****Toltrazuril****Ponazuril**

DNA-Synthesis-Affecting Drugs V: Interference with Dihydroorotate Dehydrogenase, Fig. 1 Structures of antiparasitic drugs affecting DNA-Synthesis by interference with Dihydroorotate Dehydrogenase

lymphocyte cells thus setting free the schizonts which are not protected against the host defense system in contrast to merozoites with their surface-coated ► [pellicle](#). Menoctone (=2-hydroxy-3-(8-cyclohexyl-octyl)-1,4-naphthoquinone) is active in vitro in infected bovine lymphoid cell cultures and against theileriosis in cattle in vivo.

Atovaquone exerts antimalarial and anticoccidial activity. It is used for treatment of ► [malaria](#) in combination with proguanil and shows activity in opportunistic infections in ► [AIDS](#) (► *T. gondii* cysts in the brain of mice). It has high efficacy in humans suffering from malaria after oral applications. Very recently a new drug combination atovaquone/proguanil

**DNA-Synthesis-Affecting
Drugs V: Interference
with Dihydroorotate
Dehydrogenase,**

Fig. 2 Model of
dihydroorotate
dehydrogenase as target for
anticoccidial drugs

(Malarone) was introduced for treatment of acute uncomplicated Malaria tropica. It is also effective for ► [prophylaxis](#). There are no more clinical trials of atovaquone against cryptosporidiosis.

Molecular Interactions

The action of **atovaquone** against multidrug-resistant strains of *Plasmodium falciparum* may be explained by its new mode of action being different from that of the other antimalarial drugs. It is assumed that the antimalarial actions of 2-hydroxynaphthoquinones and 4-hydroxyquinolines are identical. Their activity is directed against schizonts in lymphocytes or

against erythrocytic schizonts (► [Hemoglobin Interaction](#)/Fig. 2). There is additional activity against liver and mosquito stages of *P. berghei*. Besides, the formation of ookinets from mature gametocytes of *P. falciparum* is inhibited. As analogues of ubiquinones these compounds have structural similarity to reduced coenzyme Q, and they act through an inhibition of the electron transfer at complex III of the mitochondrial respiratory chain of parasites. Moreover, there are several reports of an inhibition of cellular respiration by 4-hydroxyquinolines and an inhibition of mitochondrial succinate dehydrogenase and NADH-dehydrogenase activities from different sources.

In isolated ► **mitochondria** from *P. falciparum* atovaquone is bound strongly and selectively to the ubiquinol-cytochrome c reductase site of the respiratory chain (= complex III). The point of block is located between the ubiquinone and cytochrome b. The inhibition can be reversed by addition of coenzyme Q. The high therapeutic index and thus the high selectivity of 4-hydroxyquinolines correlates with the lack of inhibition of cell respiration in the chicken host. The reason for this is presumably the great difference of the electron transport chains between ► **coccidia** and their vertebrate hosts. Indeed, atovaquone is 2000-fold more active against the plasmodial respiratory chain compared to the corresponding rat liver mitochondria.

There is another hypothesis for the action of hydroxyquinolines, which relies on the inhibition of pyrimidine nucleotide synthesis at the level of dihydroorotate dehydrogenase (Fig. 2). This then would result in an inhibition of ► **sporozoite** and trophozoite development in the intestinal epithelium. Indeed, a strong inhibition of pyrimidine nucleotide synthesis could be shown for amquinat, buquinolate, decoquinat, and meticlorpindol probably due to an inhibition of dihydroorotate dehydrogenase (DHOD) (Fig. 2). In ► **Plasmodium**, where ubiquinone plays an important role as an electron acceptor for dihydroorotate dehydrogenase (DHOD), atovaquone is believed to inhibit the pyrimidine synthesis at this level.

Resistance

There are high frequencies of serious drug resistance in the field against 4-hydroxyquinolines of veterinary medicine. Thus, resistance against buquinolate already appeared within 6 months. There is cross-resistance between different quinines as indication for a similar mode of action. Mitochondria from 4-hydroxyquinoline-resistant *Eimeria tenella* are insensitive to drug inhibition. The mitochondrial respiration of amquinat resistant cells is nearly 100-fold less sensitive to 4-hydroxyquinolines, but the real mechanism of resistance on the molecular level is still unknown. Until now resistance of malaria parasites against the 2-hydroxynaphthoquinone atovaquone does not play any role.

Toltrazuril

Synonyms

Baycox.

Clinical Relevance

Toltrazuril exerts high efficacies in the treatment of poultry coccidiosis. Moreover, the drug is very useful in the treatment of *Cystoisospora ohioensis* and *Isospora canis* in dogs under experimental and field conditions, *I. suis* in piglets, *Eimeria bovis* and *E. zuernii* in calves. Unlike other anticoccidials toltrazuril acts on all intracellular developmental stages of all known *Eimeria* and *Isospora* spp. In addition, toltrazuril exerts an activity against the schizogonous and gametogonic stages of *Toxoplasma gondii* in the cat (► **DNA-Synthesis-Affecting Drugs IV/ Table 1**). For extraintestinal infections of *T. gondii* in cats longer treatment periods with toltrazuril are necessary. Toltrazuril has additional activity against sarcocystosis (► **DNA-Synthesis-Affecting Drugs IV/ Table 2**).

Molecular Interactions

Toltrazuril is a symmetrical triazinetrione. Its action is directed against first and second generation schizonts, microgamonts, and macrogamonts. It has no activity against free sporozoites and merozoites. Toltrazuril probably acts by inhibiting the mitochondrial respiration and nuclear pyrimidine synthesis in the parasite. A destruction of the ► **wall-forming bodies II** can be observed in the macrogamonts. Histochemical and biochemical studies reveal that dihydroorotate dehydrogenase may act as a further target of toltrazuril (Fig. 2). There is ultrastructural evidence that plastid-like organelles are present in *T. gondii*, *Sarcocystis muris*, *Babesia ovis*, and *P. falciparum* containing protochlorophyllidae as well as traces of chlorophyll bound to the photosynthetic reaction centers PS I and PS II. These plastid-like structures have been described as membranous cytoplasmic structures containing a circular DNA molecule of 35-kb length having a plastid ancestry. It is assumed that the sensitivity of apicomplexans to toltrazuril depends on the interaction of this drug with the D1

protein, a vital constituent of the photosynthetic reaction center II.

Until now there are only reports of isolated cases of resistance against toltrazuril. Under laboratory conditions resistance is relatively difficult to achieve.

Ponazuril

Synonyms

Toltrazuril-sulfone; Marquis.

Clinical Relevance

Ponazuril treatment is approved for equine neurological disease, called equine protozoal myeloencephalitis, which is caused by *Sarcocystis neurona*. Moreover, the drug is effective experimentally against *Neospora caninum* (syn. *Hammondia heydorni*) in mice and calves, *Toxoplasma gondii* tachyzoites in cell culture and mice, and *Eimeria vermiformis* infected mice.

Molecular Interactions

Ponazuril (toltrazuril-sulfone) is the anti-protozoally active metabolite of toltrazuril. Therefore it presumably exhibits the same molecular interactions as the mother compound toltrazuril (Fig. 2).

Dog Parasites

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Dogs live since thousands of years close to humans and thus the chance of cross-infections with parasites had become possible. Table 1 lists some important parasites with a given zoonotic potential. All of them are presented by separate keywords.

Dog Parasites, Table 1 Important parasites with a given zoonotic potential

Dollo's Law

This reflects the long-held assumption, that in evolution an organism, which had changed from a complex to a simple state will never return to the complex one, e.g., a free-living stage, when having lost structures and living as a parasite, will never return to the free-living state. Recent findings, however, indicate that there may be reversal.

Dracontiasis

Synonyms

Dracunculiasis, *Dracunculus medinensis*.

Dracunculiasis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Synonyms

Guinea worm infection; Dracontiasis; Medina
worm disease; Fil d'Avicenne

General Information

Dracunculiasis is acquired by the swallowing of copepods infected with larvae of ► [Dracunculus medinensis](#) with drinking water. The larva molts and may leave the copepod to be ingested by another one. Or, the ingested L3 larva matures in

the deep tissues of humans, and as mature female migrates to a subcutaneous site (usually arm or leg). Larvae are deposited into the tissue, and because of hypersensitivity, a cutaneous vesicle is formed which may ulcerate. Upon immersion of the extremity into water, the adult projects into the ► [ulcer](#) or vesicle and releases the larvae which wait to be ingested again by copepods. Two types of lesions are produced in man, vesicles which ulcerate and subcutaneous or deep abscesses around dead adult worms. Inflammatory reaction in the microabscess includes epithelial and giant cells, lymphocytes, and plasma cells; neutrophils and eosinophils are also present close to degenerating worms. These lesions eventually calcify.

Targets for Intervention

The infective larvae of *Dracunculus medinensis* are ingested by the human host with water while they are still contained within their copepod host (*Cyclops* spp.). Figure 1 illustrates that dracunculiasis is a disease that lends itself to simple and highly effective control. The major targets of intervention are the cycle of infection and the environment of the copepod host. The approaches to control include detection of infected persons, extraction of the adult worm, prevention of contamination of water used for human consumption, and control of *Cyclops* spp. in such water collections, as well as the use of safe drinking water.

Dracunculiasis, Fig. 1 Targets and approaches for the control of dracunculiasis

Main clinical symptoms: Allergic skin reactions, skin necrosis.

Incubation period: 3–4 months.

Prepatent period: 10–14 months until emergence of the female (► [Dracunculus](#)/Fig. 3).

Patent period: Female dies usually within 2–6 weeks after emerging from the skin.

Diagnosis: Macroscopic inspection of appearing females.

Prophylaxis: Avoid drinking uncooked water in endemic regions.

Therapy: Surgical withdrawal of adult females, for treatment see Nematocidal Drugs.

Dracunculus medinensis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Classification

Species of ► [Nematodes](#).

Dracunculus medinensis, Fig. 1 Life cycle of *Dracunculus medinensis* (i.e., Medina worm, fil d'Avicenne). 1 Adults (male 4 cm, female 80 cm × 2 mm) live in the subcutaneous tissues of the final host, man, where a gravid female induces the formation of an ulcer-like sore, through which it can protrude its anterior end (with water contact). Its body wall is ruptured by pressure, allowing the gravid uterus to prolapse and release a mass of first-stage larva (L_1) – up to half a million per day. 2, 3 L_1 remain active in the water up to 1 week until being ingested by a suitable

intermediate host (copepodid crustaceans). 4–6 Inside the hemocoel of the intermediate host, the transformation to infectious third-stage larvae ($300\text{--}600 \times 15 \mu\text{m}$) occurs (via two molts) within 12–14 days (at 25°C). In general, a single larva is found inside a copepod. 7 Infection of man is effected when swallowing infected copepods in contaminated drinking water. Between 10 and 14 months are needed until a new blister in the skin appears (prepatent period). CU ► cuticle of first stage larva, E esophagus, IN intestine, NR nerve ring, PH ► phasmid cell anlage

Dragon Worm

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

See ► [Dracunculus medinensis](#), a nematode worm of humans, which is practically no more existing today, since the pathway of transmission (oral uptake of small infected crustaceans within

drinking water) is blocked due to construction of drinking water wells in endemic regions.

Dragon Worms (Dracunculidae) of Fish

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Localization

The worms are found (depending on the species) below scales, within gills, in the body cavity, or in the swimbladder of salt water and freshwater fish. They appear mostly reddish, since they suck blood.

Morphology/Life Cycle

This group of worms comprises species of the genera *Philometra*, *Anguillicola*, *Philometroides*, *Twaitia*, etc., which depending on the species contain differently sized specimens reaching a length from a few mm (under scales) until 40 cm (inside the swim bladder). They all get free motile larvae which are ingested by intermediate hosts (planktonic species, small fish). The final hosts ingest these intermediate hosts and after growth copulation occur. While after copulation males mostly die, only females wander into the swimbladder (*Anguillicola*) or at the surface (below scales) depending on the species.

Infection

Ingestion of larvae 3 bearing intermediate hosts (small crustaceans).

Symptoms of Disease

Loss of weight, weakness, secondary bacterial or fungal infections, heavy breathing, disturbances of movements; death in case of heavy infections.

Diagnosis

Inspection of feces for larvae, check of selected scales.

Prophylaxis

Avoid to feed living plankton, freeze it before; keep new fish for a while in separate aquaria (= quarantine) – especially when buying imported fish from Asia.

Therapy

Treatment of the fish by entering levamisole or fenbendazole into the aquarium (e.g., Nematol[®] of Fa. Alpha-Biocare, Düsseldorf, Germany).

Drepanidotaenia

Syn. *Hymenolepis lanceolata*, a worldwide occurring tapeworm of goose, ducks, and waterbirds, reaches a length of up to 25 cm, uses intermediate hosts (small crustaceans, e.g., *Cyclops*) and various transport hosts (water snails, e.g., Fam. Lymnaeidae).

Drepanidotaenia lanceolata

Tapeworm in the intestine of ducks.

Drepanocephalus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of echinostomatid trematodes, which are characterized by typical 27 spines in the cephalic region. They parasitize aquatic birds (mainly cormorants) on the American continent. Intermediate hosts are planorbid snails (*Planorbella trivolvis*) and, e.g., channel catfish (*Ictalurus punctatus*) in North America. In South America (Brazil) occurs, e.g., *D. spathans* in *Phalacrocorax brasilianus*, while snails of the species *Biomphalaria straminea* act as first intermediate host. Since the cercariae of *Drepanocephalus* sp. are provided with 27 spines like those of the species of the genus *Paryphostomum*, species diagnosis on the level of morphological features of the cercariae is difficult.

Drug Discovery

The drug discovery and drug development process to screen and evaluate new chemical entities (NCE) with antiparasitic activity is similar to the well-known classical way in pharma industry. These are because of a high number of excellent, recent reviews in this field and distinct problems in the area of antiparasitic drug discovery should be discussed.

The use of antiparasitic drugs is a broad field ranging from ectoparasites, like lice, up to endoparasites like malaria or African sleeping disease, indicating that each parasite needs specific and well-targeted drugs for treatment. Because of the high diverse group of parasites in this review, we focus mainly on endoparasites that belong to the group of protozoa like *Plasmodium*, *Leishmania*, *Trypanosoma*, and *Cryptosporidium*. Most of these protozoa cause diseases which affect, so-called low-income, countries in the Third World, and only a small market exists in industrialised countries affected by people traveling and contracting mostly malaria. Most of the diseases were neglected, because of low economic interest; in recent years non-profit organisations, like DnDi, MMV, Wellcome Trust, and Institute for OneWorld have taken action to bring these diseases to public awareness and to push academia and industry in private–public partnerships. This positive development has been supported by philanthropic institutions like Rockefeller and Gates Foundation allowing projects with million-dollar budgets. In recent years, product development partnerships have become the principal means, internationally, for the successful development of new medicines, and vaccines

and diagnostics for diseases that predominantly affect people in the developing world.

Drug Development Process

Development of new antiparasitic drugs is expensive, time consuming, and a complex and risky process that takes up to 10–12 years, costs in average €300–700 million Euros and requires a strict drug approval procedure. These aspects affect the willingness for the development of new drugs for neglected diseases. Figure 1 displays the major steps in drug development over 10–15 years.

The most important aspect is health impact of the final product for the target developing country patients. A literature survey of the parasitic disease literature related to the drug development process, a series of 21 independent metrics for safety, efficacy, affordability, and suitability of neglected disease drugs are published. An ideal antiparasitic drug would receive a maximum score on all criteria, what can be considered as not

realistic, while a drug with low scores on all criteria would represent a very poor product and would be selected out of the drug development process. On the basis of the scores, drug development experts discriminate valuable antiparasitic drug candidates and products are then classified as below average (less than or equal to half the maximum score for an ideal drug) or above average (more than half the maximum score) on each metric. The major four criteria in drug development will be discussed here.

Efficacy

Resistance is most crucial point and seriously affects efficacy when treating parasitic diseases. This was and is still obvious for chloroquine in malaria treatment; therefore efficacy must be measured for both the short term (cure rates) and the long term (likelihood of rapid development of resistance). Efficacy metrics are also tailored to each disease. For example, schistosomiasis treatments are assessed for whether they are active

Drug Discovery, Fig. 1 Drug discovery process (Modified according to Nwaka and Ridley 2003)

Drug Discovery, Fig. 2 Drug development process to market authorisation (Modified according to Nwaka and Ridley 2003)

against all common strains and species, and lymphatic filariasis treatments are assessed for activity against both larval and adult worms.

Safety

In principal, the safety concern should be on the same high level in Western or Third World countries. However, for antiparasitic drugs we have to consider a different safety profile, because of the low number of available drugs and cost-benefit analysis, the non-use of a medicine could be more harmful than the potential side effects. It must be under serious consideration to apply Western settings and safety assessment must take into account

the incidence and severity of adverse effects (as usually experienced and reported). In that particular case a pharmacovigilance network should be installed to report about adverse events after administration to patients by trained physicians, but also given as over-the-counter drug. The lack of modern public health infrastructure explains high non-prescription use, but also buying drugs illegally from the black market.

Market Costs and Suitability for Developing Country Use

No medicine can be as good as it is not available on the market. Therefore the price for antiparasitic

can meet the realistic price for development and production in industrialised countries, but would be rather inaccessible for the majority of patients in Africa and Asia. The average budget in a so-called low income country allows public health care by US\$4 per person and year. As an example artemisinin-based chemotherapy costs US\$2–2.5 per dosage, and artemisinin covers US\$1–1.5 from these costs. Annually each patients has to follow 10–12 treatment courses summing up the total price to US\$25–30 per year.

Logistically suitability has to be installed and is depending on several indices, including:

1. Ease-of-use for patients and health care workers, e.g., dosing intervals, length of treatment required, availability of oral formulations
2. Appropriateness to developing country health systems, e.g., requirement for cold chain, or for hospital-based administration
3. Percentage of the affected patient group covered by the therapy, e.g., adults and
4. Children, or only adults; all patients, or only second-stage or severely ill patients.

This index was also tailored to each disease, but special diseases like tuberculosis, what is not a parasitic disease, needs a long term treatment covering other additionally indices, while antimalarials were additionally assessed for usefulness in pregnant women and paediatric patients, who make up the majority of malaria mortality figures.

For latest literature information please contact the author Professor Dr. Kayser (Fig. 2).

Drug Targets

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In recent times, various contemporary approaches to identify and characterize drug targets in helminth parasites have been developed: (a) rapid

sequencing of parasite genomes using next-generation sequencing machines like 454 and Illumina to quickly spot and identify unique/divergent genes; (b) proteomic analysis (2D, mass spectrometry, SILAC, etc.) of the parasites or part of the parasites; (c) biophysical and biochemical characterization (X-ray, crystallography, UV-visible spectroscopy, circular dichroism spectroscopy, isothermal titration calorimetry, neurobiology, enzymology, etc.) of drug targets; (d) localization study and RNA interference of genes to know the essentiality and functions of unknown genes in nematode model organism called *C. elegans*; (e) in vitro screening of hits against drug targets in culture plates using MTT assays, NTS assay, etc.; and (f) in vivo screening of leads (obtained after multiple screening and selecting the best hits) in appropriate animal model for specific helminthiasis.

Drug Targets for Helminthic Diseases

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The development of new drugs depends today on clearly defined goals, since spreading of resistances occurs in very short periods and research just by screening test affords long time. Thus, drug targets must be clearly defined and selectively chosen for experiments. Recent drug targets are listed in the following review.

Rana AK, Misra-Bhattacharya S (2013) Current drug targets for helminthic diseases. *Parasitol Res* 112:1819–1832

Drugs

Synonyms

Agent; Compound; Medicament; Product; Substance

Definition

Drug can be broadly defined as any chemical compound that affects living processes and is used in the diagnosis, prevention, treatment (cure) of disease(s), or for controlling or improving any physiological or pathological disorder, or for relief of pain in animals and humans.

Drugs Against Microsporidiosis

General Information

Microsporidians are eukaryotes of ancient origin (lack of ► [mitochondria](#)) and obligate intracellular parasites entering host cells via a ► [polar tube](#) within a spore. The organisms are ubiquitous and may occur in humans and a wide range of animals (wild, fish, and arthropods) but also dogs and other domestic animals commonly associated with humans. Today, there are no efficient control measures for prevention of ► [microsporidiosis](#) in humans and ► [animal reservoirs](#). ► [Spores](#) seem to be resistant to various physical effects such as

sonification, freezing or thawing, ultraviolet or gamma radiation.

Humans

Serious microsporidiosis may develop in immunocompromised individuals (e.g., ► [AIDS](#) patients, travellers going to tropical areas). Ocular infection is manifest by conjunctival, corneal, and/or stromal invasion, predominantly by *Encephalitozoon hellem*, and *Vittaforma cornea* (syn. *Nosema corneum*). Intestinal infections are due to ► [Enterocytozoon bieneusi](#), *Encephalitozoon intestinalis*, and ► [E. cuniculi](#). Clinical signs may be severe diarrhea, malabsorption, and wasting. Disseminated infections may be produced by *E. hellem*, *E. cuniculi*, and *Pleistophora* spp. and are often accompanied by concurrent HIV infection (Treatment of Opportunistic Agents/Drugs Acting on Cryptosporidiosis of Mammals and ► [Antidiarrhoeal and Antitrichomoniasis Drugs/Drugs Acting on Giardiasis](#), respectively).

Pathology

Immunosuppressed humans have been sentinels of microsporidial infection, with enteric, neurologic, ocular, and pulmonary manifestation being recognized. Their symptomatology, pathology, and differential diagnosis, based on ultrastructure and the polymerase chain reaction, has been widely established. Microsporidiosis appears to be a common asymptomatic infection, that is not clinically recognized; about 10 % of animal handlers were reported to have antibody to ► [Encephalitozoon](#) sp. The organism grows intracellularly, destroying the infected cells. There is little inflammation. The Brown-Brenn stain (Gram-stain for tissues), basic fuchsin, toluidin blue, Azur II-eosin, the Warthin-Starry silver impregnation, and polarization facilitate recognition of ► [microsporidia](#) in tissue sections. Tissue imprints (smears), dried, fixed, and stained as for blood smears, are useful for diagnosis of corneal and conjunctival lesions. Stool and sputum

smears can be stained with a modified ► [trichrome stain](#) employing chromotrope 2R or with a fluorochrome ► [chitin](#) stain, such as Calcofluor.

A fatal disseminated infection of a 4-month-old thymic alymphoplastic baby with *Nosema connori* involved the smooth musculature, skeletal muscles, the myocardium, parenchyma! cells of the liver, lung, and adrenals. *Encephalitozoon* sp. was isolated from the cerebrospinal fluid of a 9-year-old Japanese boy with meningoencephalitis who recovered (Matsubayashi). Intestinal microsporidiosis has been described in several patients with AIDS due to *Enterocytozoon bieneusi* also with cholangitis and due to *Encephalitozoon (Septata) intestinalis*. The patients had ► [diarrhoea](#), with ► [weight loss](#) from malabsorption. Inflammation was minimal and the diagnosis was made ultrastructurally. Disseminated *Encephalitozoon cuniculi* infection was noted and *E. hellem* had been isolated from AIDS patients with nephritis and prostatitis and from others with keratoconjunctivitis, bronchitis, and sinusitis. Microsporidial myositis due to *Pleistophora* and *Trachypleistophora hominis* was reported in patients with AIDS. Intraocular microsporidiosis was diagnosed from the cornea next to Descemet's membrane with a subacute to granulomatous inflammatory reaction; other HIV-negative cases with corneal stromal infection were linked to *Nosema oculorum* (possibly *Vittaforma corneum*).

Treatment

Treatment is problematic since the gram-positive staining spores (most familiar stage of microsporidia) are resistant to most drugs (► [Treatment of Opportunistic Agents](#)/Table 1). Several topical antimicrobial and anti-inflammatory drugs have been used for treating ocular disease such as keratoconjunctivitis. **Topical drugs** such as propamidine isethionate or the water-soluble fumagillin derivative Fumidil-B (eyedrops) may resolve ocular symptoms caused by *E. hellem*, which reoccurs, however, when treatment is stopped indicating a static rather than a

cidal action of drugs. For lesions due to *V. corneae*, topical therapy is generally not effective and keratoplasty may be required. Oral administration of **albendazole** may improve ocular, nasal, and enteric symptoms; the drug has a marked static effect on intestinal microsporidians like *Ent. bienersi* and *E. intestinalis*. The latter species proves more susceptible to treatment with albendazole. The drug seems to inhibit polymerization of microtubules within intranuclear spindles in dividing nuclei only, and for that reason growth of parasites will continue in the absence of ► **nuclear division**. In the current situation almost nothing is known about epidemiology of human microsporidiosis; an open question is whether microsporidians in man are solely human infections or are some episodes of zoonotic origin.

Fish

With respect to chemotherapy of microsporidiosis in fish, it was shown that the antibiotic **fumagillin** acts against *Glugea plecoglossi* in the Japanese ayu (*Plecoglossus altivelis*), but in some cases the mortality of treated fish was higher than that of untreated fish. The mode of action of fumagillin is thought to inhibit DNA or RNA synthesis. More recent investigations have shown that a symmetric triazine **toltrazuril** and an asymmetric triazine (HOE 092V) kill the merogonic and the sporogonic stages of the microsporidian *G. anomala*. The drugs are also highly active against other fish and crayfish parasites. As revealed by ultrastructural investigations, the effects of the triazine derivatives on *G. anomala* comprised a decrease in the number of ribosomes, enlargement of the smooth ER, depletion of the nuclear membrane, and destruction of the nuclear structures. In a further study it was demonstrated that different **benzimidazole** derivatives (albendazole, mebendazole, and fenbendazole) disturbed the intracellular development of the microsporidian *G. anomala* by damaging its merogonic, sporogonic, and prepore stages as well as the mature spores.

Drugs Against Sarcocystosis

► *Sarcocystis* spp. are obligate, heterogeneous coccidian parasites. Definitive host may be carnivores, felidae, humans, and primates. Their asexual reproduction may occur in herbivores (horse, cattle, sheep, goat, camel), omnivores (pigs, humans), and also birds (chicken, ducks). Consumption of feed contaminated with sporocysts (oocysts) from the feces of the definitive host leads to infection of herbivores.

Pathology and Treatment

Experimental sarcocystosis in cattle (*S. bovicanis*) or that of horses (*S. equicanis*) has been associated with acute and chronic myositis caused by intramuscular sarcocysts. Long-term treatment with orally administered pyrimethamine, and trimethoprim + sulfamethoxazole is necessary to achieve remission of clinical signs. This can be applied also to cases of naturally occurring equine protozoal myeloencephalitic (► **EPM**) caused by *S. neurona*. The treatment lasted between 45 and 211 days; adverse effects in horses were mild to severe, including ► **abortion**. **Halofuginone** (► **Coccidiocidal Drugs**, Table 1) appears to be effective against acute sarcosporidiosis in goats and sheep at 0.67 mg/kg on 2 successive days. In humans, who may serve as accidental intermediate host for several unidentified *Sarcocystis* spp. sarcocysts have been found in striated muscles. Their clinical significance is unknown in naturally occurring life cycles. For **control** of sarcocystosis, carnivores should be excluded from animal houses, and from feed, water, and rearing facilities for livestock or dead livestock. Cooking or heating (60° C for at least 20 min) of contaminated material will kill sarcocysts.

Vaccination

There is no protective vaccine against sarcocystosis in animals or humans.

Drugs with Unknown Antiparasitic Mechanism of Action (Achim Harder)

Structures

Figure 1.

DL-Propranolol

Clinical Relevance

The antiparasitic activity of propranolol is directed against ► *Giardia lamblia*.

Nitrobenzamides

Important Compounds

Dinitolamide, Zoalene, Nitromide.

Clinical Relevance

Dinitolamide, zoalene have activity mainly against first and second generation schizonts of *Eimeria tenella* and *E. necatrix*. They have only limited effects against *E. acervulina*. They do not interfere with the immunity of chicken hosts. Nitrobenzamides are assumed to act as a nicotinamide antagonist.

Diclazuril/Clazuril

Clinical Relevance

Diclazuril and clazuril belong to 1,2,4-triazine-derivatives. They have broad-spectrum activity in ► *Eimeria* infections. They exert additional activity against ► *Neospora caninum* ► tachyzoites in cell cultures. The mode of action is unknown. The activity of diclazuril is directed only against specific endogen stages of *Eimeria* species. Thus, diclazuril is active against second generation schizonts of *E. acervulina*, *E. mitis*, and *E. necatrix*, against gamonts, late schizonts of *E. brunetti*, zygotes of *E. maxima* and first and second generation schizonts, and sexual stages of *E. tenella*. The ► sporulation becomes delayed by diclazuril.

Febrifugine

Clinical Relevance

Febrifugine is an antimalarial drug from traditional Chinese medicine.

Pyronaridine

Clinical Relevance

Pyronaridine has high efficacy in clinical studies in China against chloroquine-resistant *Plasmodium falciparum*. There is cross-resistance to 4-aminoquinolines and quinolinemethanol antimalarials. Morphological effects on ► mitochondria, endoplasmic reticulum, and ribosomes can be observed. Food ► vacuoles are probably a primary target of pyronaridine.

Halofuginone

Clinical Relevance

Halofuginone is a quinazolinone derivative. It is an alkaloid originally isolated from the plant *Dichroa febrifuga*. It is effective against the six pathogenic *Eimeria* spp. of chicken. Halofuginone has an influence on sexual first-generation ► schizogony. It specifically suppresses the skin collagen synthesis in mammalian cells in vivo resulting in an increase in skin fragility. In vitro the incorporation of radiolabelled proline into collagen by avian skin fibroblasts is impaired. Thereby, the expression of $\alpha 1$ gene of collagen type I is specifically depressed but not that of collagen type II in skin fibroblasts and growth-plate chondrocytes. This results in a decrease in synthesis of collagen. The mechanism of action against *Eimeria* spp. is unknown at present. Furthermore, halofuginone has been used in *Theileria parva* and *T. annulata* infections in cattle. The activity is directed against schizonts in lymphocytes. Thereby, infected lymphocytic cells are destroyed setting free the schizonts, which in contrast to merozoites with their surface-coated ► pellicle are not protected against the defense system of the host. Halofuginone has

**Propranolol****Diclazuril****Zoalen****Letrazuril****Febrifugine****Pyronaridine****Halofuginone****Hetolin**

**Cyclosporin A****Quinuronium Sulfate****Amicarbalide**

Drugs with Unknown Antiparasitic Mechanism of Action (Achim Harder), Fig. 1 Structures of antiparasitic drugs with unknown mechanism of action

additional activity against *Cryptosporidium parvum* in calves.

Halogenated Hydrocarbons

Clinical Relevance

The halogenated hydrocarbons carbon tetrachloride, hexachloroethane, tetrachloroethylene and hexyloesorcinol were used until very recently in veterinary medicine. Now they are no longer used because of mutagenic properties. Hetol (= hexachloroparaxylene) was used to a limited extent in veterinary medicine against ► *Fasciola hepatica* infections and for human ► *Clonorchis sinensis* infections (► [Energy-Metabolism-Disturbing Drugs](#)/Table 2). However, it is characterized by serious side effects.

Hetolin

Clinical Relevance

Hetolin is a specific compound against ► *Dicrocoelium dendriticum* (► [Energy-Metabolism-Disturbing Drugs](#)/Table 1) with erratic efficacies.

Cyclosporin A

Clinical Relevance

The antiparasitic activity of cyclosporin A was discovered in 1981. The antiprotozoal activity is directed against ► *Leishmania* spp., *Toxoplasma* and ► *Plasmodium*. In addition, cyclosporin A has anticestodal and antischistosomal activity. The latter is directed against schistosomes. Here

the compound has a long-lasting prophylactic effect up to 100 days before infection. After treatment the number of worms is reduced. Immature worms and female worms are more affected than male worms. The use of cyclosporin A would mean important qualitative progress in the control of schistosomiasis since there would be protection by a single dose over a good part of the transmission season. A correlation between the antiparasitic and the immunosuppressive effects of cyclosporin A seems unlikely, since cyclosporin analogs with antischistosomal activity show only minor immunosuppressive activity. Cyclosporin A has lethal effects in vitro against schistosomes. Cell-mediated immunity does not play a role in the antischistosomal action of cyclosporin A. Furthermore, the compound has antifilarial activity and is used in human medicine as an immunosuppressing drug.

Quinuronium Sulfate (= Acaprine), Amicarbalide

Clinical Relevance

Babesiosis of cattle may be controlled easily by these two drugs. A single parenteral treatment results in the disappearance of clinical symptoms and premunity against, e.g., *Babesia divergens*. In general, however, improvement of parasitaemia is obtained only after several treatments with higher dosages.

DTP

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Daily transmission potential of vectors (such as mosquitoes) of given parasites or of other agents of diseases.

Duncker's Muscle Cones

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Stages of the digenetic trematode ► *Alaria alata* (► *Diplostomatidae*) in the muscles of pigs. This term describes mesocercariae, which had been fed by pigs within second intermediate hosts (frogs, frog larvae). Thus pigs became ► *paratenic hosts*.

Duncker's Muscle Fluke

Mesocercariae of ► *Alaria allata* in pig muscles.

Duplicidentata

Order Lagomorpha (hares, rabbits)
Simplicidentata (rodents = rats, mice, hamster).

Dutton, John Everett (1874–1905)

English scientist, who discovered the tick-borne relapsing fever (due to transmission by *Ornithodoros moubata*). His friend, the Canadian scientist J.L. Todd, honoured Dutton by naming the agent of this disease *Spirochaeta* (now *Borrelia*) *duttoni*. Dutton died at only 31 years of age from this disease on the February 5, 1905, while his colleague survived. The louse-borne relapsing fever was detected by ► *Obermeier*.

Duttonella

Subgenus of ► *Trypanosoma*.

Dysentery

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Greek name for an often bloody diarrhea.

Dysenterias

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *dysenteria* = intestinal bloody flu.

The symptoms of this disease start with slight fever, abdominal pain, vomiting, however, increases during next days of infection, whereby the agents of disease (bacteria, parasites) enter the intestinal wall. Many authors claim, for the symptoms of this group, that bloody components are essential diagnostic tools.

1. **Dysentery endemic:** due to *Entamoeba histolytica* (intestinal phase).
2. **Dysentery hepatica:** due to *Entamoeba histolytica* (liver abscess).
3. **Dysentery fulminans:** stormy with heavy water loss.

4. **Dysenterya maligna:** life threatening, often deadly form mostly due to bacterial invasion in tissues.

Dyskinetoplastic

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Stages of *Trypanosoma* species, which do not show a ► [kinetoplast](#) after Giemsa staining. This does not mean that there is no DNA in the long mitochondrion. Apparently there is, however, not enough DNA available in the mitochondrion (close to the basal apparatus of the flagellum) in order to become stained and thus visible in Giemsa-stained blood smear preparations as a reddish dot.

Dyskinetoplastic Stage

The ► [kinetoplast](#) of some trypanosomatids loses its DNA content in some developmental stages these stages may survive in mammals, but not in the vector.

Dyskinetoplastic Trypanosomes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes *Trypanosoma* species or peculiar stages, which have lost their mitochondrial DNA (mtDNA, kinetoplast or kDNA). Examples for dyskinetoplast species are *Trypanosoma equi* and *T. evansi*.

Ebola

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This virus (named after a river close to the West African village of the first human case) leads to a hemorrhagic fever that kills about 80–90 % of infected persons. The original hosts are apparently fruit eating bats and small monkeys, which belong to the food of the people in endemic regions in West Africa. Transmission occurs by oral uptake of contaminated food and by contact to body fluids and feces. Thus transmission by licking flies (► [Musca](#), etc.) cannot be excluded (date November 2015).

Ebola Transmission

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This virus – named after a side river of the Congo River – is thought to occur in fruit bats and in small monkeys without lethal symptoms. Transmission among humans occurs by contact to contaminated body fluids (e.g., blood, lymph, sweat). Thus transmission cannot be excluded, if flies get in contact with such sources, since it was shown by Gestmann et al. (2012) and Förster et al. (2012) that flies may easily transport and carry large numbers of bacteria, fungi, and parasites.

Ecdysis

Name

Greek: *ecdysis* = hatch.

During growth arthropods have to discharge several times their cuticle. ► [Ecdysteroids](#), used during molt of ► [nematodes](#) and arthropods.

Ecdysteroid Receptor

Synonyms

EcR

General Information

Genomic ecdysteroid effects in insects and crustaceans are mediated via an intracellular ecdysteroid receptor (EcR). This receptor belongs to the superfamily of nuclear receptors and is related to all vertebrate steroid hormone receptors. In its functional form the EcR is usually a heterodimer of EcR and another transcription factor, belonging to the same superfamily, which is called ultraspiracle (USP) and which is a homologue to the vertebrate retinoid X receptor (RXR). EcR and USP are phosphoproteins and can occur in different splice variants. They possess a ligand (= ► [Hormone](#)) binding domain (LBD), a DNA binding domain (DBD), and a transactivation domain as well as interfaces for dimerization, interaction with ► [heat shock proteins](#) and comodulators, and for nuclear transport.

Highest ligand affinity has been shown for ponasterone A and muristerone A, followed by 20-hydroxyecdysone (► [Ecdysteroids](#)). Depending on the insect taxon high affinity for non-steroidal molting hormone agonists was shown. The EcR expression is under control of its own ligand.

► [Nematodes](#) are claimed to be closely related to arthropods according to molecular criteria and ► [ecdysteroids](#) have been demonstrated in this ► [helminth](#) group unequivocally (► [Ecdysteroids](#)). Therefore, one could assume the same mode of action of ecdysteroids and thus the presence of ecdysteroid receptors also in nematodes, but so far all attempts to demonstrate ecdysteroid-binding proteins by ligand binding were unsuccessful. Using consensus sequences of the nuclear receptor superfamily for screening in ► [Caenorhabditis elegans](#) libraries, cDNA clones were found with high sequence identity to steroid hormone receptors. Since orphan receptors and other transcription factors are also members of this superfamily, this is

no proof for the existence of an ecdysteroid receptor in *C. elegans*. Expression of these cDNA clones and subsequent binding studies must be performed before an unequivocal proof for the presence of an ecdysteroid receptor in *C. elegans* is valid.

Gene Regulation

The concept of gene expression by steroid hormones was originally derived from studies on puff induction in giant [▶ chromosomes](#) by ecdysteroids and subsequently improved. Functional ecdysteroid receptors are essential for gene regulation by ecdysteroids and induce a set of gene products. As early responses transcription factors are induced which are members of the nuclear receptor superfamily themselves.

Implications

Non-steroidal molting hormone agonists which bind to the functional ecdysteroid receptor are used for insect pest control by evoking precocious and incomplete molting. Successful applications of ecdysteroid agonists and antagonists to nematodes were not described so far. The ecdysteroid receptor in combination with RXR is used as an ecdysteroid-inducible expression system in mammalian cells.

Ecdysteroids

Synonyms

Molting hormones

General Information

The name ecdysteroids refers to a class of steroid hormones whose main function the regulation of [▶ ecdysis](#) in arthropods. Ecdysteroid is a generic name for a total of more than 120 different polyhydroxylated steroids present

either in plants (phytoecdysteroids), invertebrates (zooecdysteroids), or both. The ecdysteroids are present in all invertebrate phyla and thus represent the most widespread steroid hormones. The molecular weight is between 464 (e.g., ecdysone, ponasterone A) and 480 (20-hydroxyecdysone).

Structure

In contrast to vertebrates, the invertebrates studied so far are unable to synthesize sterols *de novo* and are therefore dependent on the presence of cholesterol or related sterols. Another difference is the presence of a full side chain as in cholesterol. Zooecdysteroids are therefore mainly C27 steroids, in contrast to the vertebrate steroid hormones (C18, C19, and C21) (Fig. 1). All ecdysteroids bear a *cis*-fused A/B ring junction which is again different from the situation in vertebrates (*trans*-fused A/B ring junction). A further difference to vertebrate steroid hormones is the good water solubility of ecdysteroids, caused by the high number of hydroxyl groups. Ecdysteroids can occur either in free form or as conjugates. The position of [▶ conjugation](#) as well as the main groups which are conjugated with ecdysteroids are shown in Fig. 1.

Like in vertebrate steroid hormone research, non-steroidal molting hormone agonists (bisacylhydrazines) are useful tools for the study of hormonal action and for interference with molting processes. Recently molting hormone antagonists (cucurbitacins; triterpenoids of plant origin) have also been described.

Physiological Function

In contrast to insects and crustaceans, much less information is available on the physiological roles of ecdysteroids in other phyla. Among parasites there are some data on presence, titer, and putative functions available for [▶ cestodes](#) and [▶ trematodes](#) but most information has accumulated for [▶ nematodes](#). Analogous to arthropods, there are mainly 2 processes, which are probably regulated by ecdysteroids in nematodes, i.e., development

Ecdysteroids,**Fig. 1** Ecdysteroids. (a)

Structure of ecdysteroids (20-OH-ecdysone, ponasterone A) and primary synthesis products. Arrows indicate preferential sites of conjugation with phosphate, fatty acids, acetate, glucosides, glucuronides and sulfates. (b) Representative of the group of nonsteroidal molting hormone agonists

**Non-steroidal molting hormone agonist**

and reproduction. At least in some nematodes there is a clear correlation between titer of ecdysteroids and the molting cycle and there is also an effect of ecdysone on reinitiation of meiosis, on differentiation during early embryogenesis, cell rearrangement during gastrulation, and on ► [fecundity](#).

Implications

Non-steroidal molting hormone agonists induce precocious and incomplete molt and are used for insect pest control. High concentrations of ecdysteroids are deleterious to insects (hyperecdysionism) and also kill nematodes both *in vivo* and *in vitro*. Certain amines and amides inhibit phytosterol dealkylation in insects and free-living nematodes and steps in the ecdysteroid biosynthetic pathway in insects and are powerful schistosomicidal agents.

Echenebothrium dubium

Tetraphyllid tapeworm in Chondrichthyes (rays).

Echidnophaga gallinacea

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The name of this 2.5 mm-sized so-called crest-flea of birds comes from the old name of the ant-hedgehog (*Echidna hystrix*), on which the first specimen of this flea was detected. *Echidna* is a Greek mythical monster and Greek: *phagein* = feeding. Besides birds, *E. gallinacea* parasitizes worldwide at many host species including man.

Species	Mating	Start of Copulation	Copulation	After Copulation
<i>Xenopsylla cheopis</i>				
<i>Echidnophaga gallinacea</i>				
<i>Tunga penetrans</i>				
Males: small, green Females: large, red Skin: dotted, yellowish				

Echidnophaga gallinacea, Fig. 1 Diagrammatic representation of the mating of three flea species (females red, males green). In *E. gallinacea* and *T. penetrans* the females enter totally or partially into the skin

Echidnophaga gallinacea, Fig. 2 Light micrograph of a male flea (Prof. Dr. Schuster, Dubai)

Echidnophaga gallinacea, Fig. 3 Light micrograph of a female flea (Prof. Dr. Schuster, Dubai)

Since the females attach for a long time for feeding at the skin of their host, they were often erroneously kept for sand fleas (► *Tunga penetrans*). The smaller males mate with the skin-fixed females for 15 min. The mouthparts of females are used as anchor and form a deep hollow, from which the English common name “tight-stick-flea” derives.

Soon after the artistical copulation, the male hangs back down in the air; the female starts to lay eggs (about 11–14 per day), which fall onto the soil for further development. Besides *E. gallinacea*, 20 other species are described (e.g., *E. larina* and *E. aethiops* also occurring in Africa) ► [Fleas](#) (Figs. 1, 2, and 3).

Echinocephalus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of digenean trematodes of freshwater fish
(e.g., *E. caripiae*) in carps.

Echinocephalus caripiae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Common gnathostomid nematode species
infecting the common carp (*Cyprinus carpio*).
The adults measure only 0.8 mm × 0.28 mm.
This species found in Egypt is closely related to
E. overstreeti and to *Anguillicola globiceps*. Fur-
ther species are: *E. daileyi* (5–6 mm), *E. uncinatus*
(2–3 mm), *E. sinensis* (1–3.5 mm), *E. multidentatus*
(1.6 mm), *E. janzeni* (1–3.3 mm), and *E. southwelli*
(2 mm).

Echinocephalus Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This genus which belongs to the family of
Gnathostomidae ► *Gnathostoma spinigerum*

comprises about 10 valid species which are lim-
ited primarily to marine and freshwater stingrays.
Recently, *E. caripiae* was described in the carp
Cyprinus carpio in Egypt. The adult worms are
rather small reaching at the maximum only
5–6 mm in males and 5–8 mm in females in
some species (e.g., *E. daileyi* in *Potamotrygon*
circularis) but may also be tiny as it is in
E. caripiae (♂ = 0.8 mm; ♀ = 0.9–1 mm).

Echinochasmus

Genus of ► [Trematodes](#).

Echinochasmus perfoliatus

Species of the trematode order Echinostomatida.

Echinocirrus melis

One centimeter long echinostomatid flukes in the
intestinal system of hedgehocks.

Echinococciasis

► [Echinococcus](#); syn. ► [Echinococcosis](#).

Echinococcosis

Pathology

Echinococcus granulosus is the causative agent of
cystic ► [hydatid disease](#) or cystic echinococcosis
whereas infection with *E. multilocularis* in man

Echinococcosis, Fig. 1 Section through a human liver with the alveoles of *E. multilocularis*. (a) Total view, (b) Section through small strands of *E. multilocularis* in the liver

leads to the more aggressive form of alveolar echinococcosis (Figs. 1 and 2). In both cases, the primary site of contact with the parasite is the mucosal surface of the host's gastrointestinal tract. Echinococcosis is contracted by the inadvertent ingestion of eggs from the feces of dogs or other carnivores. Thus humans serve as intermediate hosts instead of normally, sheep, mice, or other herbivores. Larval cysts or ► [hydatids](#) can be found in many tissues, most often in the liver, lung, mediastinum, and peritoneum, giving rise only to pericystic fibrosis when intact. Hydatid cysts attain a large size because of asexual reproduction and proliferation of the innermost cyst layer, the germinal epithelium. In *E. granulosus* small protoscolices develop in the hydatid cysts with suckers, hooklets, and calcareous bodies. Detached brood capsules and sometimes daughter cysts develop, again with internal multiplication; the gross appearance may be one of a bunch of grapes of various sizes. In *E. multilocularis*, the external laminated membrane of the cyst is incomplete and the inner germinal epithelium proliferates diffusely in an alveolar pattern, spreading like a neoplasm through the human liver, which is destroyed (► [Pathology](#)/Fig. 16, 29E,F). Folded laminated membranes are usually present. Protoscolices are rarely found in humans, although they are common in natural hosts. The cysts of *E. vogeli* usually contain primitive scolices. Production of lesions by all species depends on the location, number, and state of the cysts. Slow seepage of cyst fluid may lead to seeding of new

Echinococcosis, Fig. 2 Liver of a sheep with numerous hydatids of *E. granulosus*

areas, and cystic metastases to brain and lung can occur. Sudden hydatid cyst rupture can produce ► [anaphylactic shock](#). ► [Eosinophilia](#) accompanies the infection. Molecular immunopathology is reviewed in detail by Gottstein and Hemphill.

Immune Responses

The cellular and humoral ► [immune response](#) in humans in response to migrating oncospheres and established metacestodes varies enormously as evidenced, for example, by different antigens recognized by individual patients with different courses of disease. Hydatid growth despite the presence of humoral and cellular anti-metacestode

immune responses may result from the variation or downregulation of the parasite's antigens or from active immunomodulation by these ► [cestodes](#).

B Cells and Antibodies

Most serological studies in humans were performed to monitor patients after long-term chemotherapy or postoperatively. In cystic echinococcosis strain variations of the parasite as well as genetic differences between host populations may significantly affect the antibody response. For example, conventional serological tests were often negative in patients from Kenya or in patients with lung localizations of the cysts. However, rapid seroconversion was observed in most of these patients early after treatment arguing in favor of immunosuppressive mechanisms which are reverted after surgical removal of the cyst. Much emphasis was given to the determination of parasite-specific antibody isotypes. However, only in the case of IgE has a significant (negative) correlation with the response to chemotherapy been reported. IgE bound to basophils may be involved in anaphylactic reactions upon preoperative or intraoperative cyst rupture.

In most patients with alveolar echinococcosis parasite-specific immunoglobulins of all isotypes can be measured at diagnosis and an association with hyperglobulinemia has been reported. Although protoscoleces and oncospheres of *E. multilocularis* can be lysed by antibody-mediated complement interaction in vitro, antibodies appear unable to control parasite proliferation in vivo. This inability may be due in part to complement-neutralizing factors released by the ► [metacestode](#) or to the inactivation of C3 as it enters the metacestode tissue. Antibodies are produced against many different proteins of the parasite, and some of these antigens were postulated to critically participate at the host-parasite interplay. For example, antibodies against the protein Em2, localized in the laminated layer of the metacestode, were found to be associated with disease susceptibility in experimental murine alveolar echinococcosis. While in resistant C57BL/10 mice anti-Em2 antibodies of the IgG3 and IgG1 isotype were synthesized, only low levels of anti-Em2 IgG2a were detected in susceptible AKR and C57BL/6 mice.

T Cells

In cystic echinococcosis patients there was no correlation between the detection of specific antibodies and the lymphoproliferative response to *E. granulosus* antigens. The fact that seronegative patients showed a positive proliferation assay and vice versa was taken as an argument for the existence of different pathways initiating humoral or cell-mediated responses. In murine cystic echinococcosis a marked reduction of the mean T cell percentage combined with an increase in suppressor activity was reported. An impairment of the ► [host response](#) by the formation of anti-MHC antibodies or by parasite-derived immune-suppressive or -modulatory substances may account for the enhanced susceptibility to mycobacterial infections close to the parasite lesions. In long-term infected BALB/c mice a higher percentage of CD4⁺ T cells in peripheral blood and a relative increase of CD8⁺ T cells in the spleen was observed. These cells appeared to be activated, because they showed a high level of interleukin-2 receptor expression. The finding that PBMCs from patients responding well to chemotherapy produced significantly more IFN- γ and less IL-4 and IL-10 than cells from partial and low responders, indicated an implementation of Th1 cells in protective immunity.

In patients with alveolar echinococcosis the lymphoproliferative response to *E. multilocularis* antigens was highest in cured patients who had undergone radical surgery and significantly lower in patients with partial or no resections. A protective role of T cells has been found in murine models of alveolar echinococcosis. Depletion of T cells or the infection of nude or SCID mice resulted in enhanced metastatic formation and development of *E. multilocularis* accompanied by a drastically reduced host-tissue reaction. *E. multilocularis* infection of permissive mouse strains resulted in the depletion of T-dependent zones of lymphoid organs and thymic involution during rapid growth of the metacestode. Although the responsible mechanism has not yet been defined, activated macrophages adhering to the metacestodes in vivo and/or immunomodulatory products of the parasite may account for it. Immunosuppression in murine alveolar echinococcosis

appears to be a more general phenomena since there was an enhanced frequency of malignant sarcomas in A/J mice infected with *E. multilocularis* when compared to noninfected controls.

Analysis of cytokine mRNA expression revealed the enhanced production of Th2-type factors such as IL-3, IL-4, IL-10, and predominantly IL-5 in stimulated cells of patients with alveolar echinococcosis. In murine alveolar echinococcosis there was an enhanced production of IFN- γ , IL-2, IL-5, and IL-10 by stimulated spleen cells in vitro over the first weeks of infection which was almost completely suppressed at 21 weeks of infection. Analysis of the local intrahepatic periparasitic cytokine expression in tissues of patients showed an enhanced expression of IL-1, IL-6, and TNF by activated macrophages. These findings together with the observation that treatment of SCID mice with TNF promoted the formation of granulomatous changes around larval cysts argue for an involvement of the locally secreted proinflammatory cytokines in the development of periparasitic granulomas and fibrogenesis. In resistant hosts activated macrophages appear to kill protozoa by arginine-dependent generation of reactive nitrogen intermediates and other, ill-defined destructive effects on the parasite-protective laminated layer surrounding the oncospheres and vesicular cysts.

The genetic basis for either host resistance (no immunosuppression?) or susceptibility ([► Immune Suppression?](#)) is still unclear. Preliminary investigations showed that the frequency of certain HLA allelels (HLA-DR13) was increased in patients with a regressive course of disease after therapy compared to controls or patients with progressive alveolar echinococcosis. However, since inbred mice of the same H-2 haplotype differ significantly in their susceptibility to *E. multilocularis* there are obviously other, non-MHC-linked genes contributing to the disease susceptibility.

Main clinical symptoms in humans: Liver dysfunction, lung problems, ascites, [► abdominal pain](#).

Incubation period: Years.

Prepatent period: Years.

Patent period: Years.

Diagnosis: Serologic tests, computer tomographic analysis of liver and other organs, [► Serology](#).

Prophylaxis: Avoid contact with infected final hosts (dog, fox, cat).

Therapy: In *E. granulosus* infections hydatids may be removed by surgery, while it is **not** recommended in alveolar cysts of *E. multilocularis* since the eventual setting free of undifferentiated cells initiates metastasis-like formation of new cysts (thus biopsies are strongly forbidden). Chemotherapy see [► Cestodocidal Drugs](#), [► Nematocidal Drugs, Animals](#) and [► Nematocidal Drugs, Man](#) (Albendazole, Mebendazole).

Echinococcus equinus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This not-well-documented species occurs in Africa and is considered as a “cryptic” species of *E. granulosus*. However, since tissue cysts were found (e.g., in zebras) in complete absence of domestic dogs (as potential final hosts), it is suggested by several authors that there should exist a wildlife cycle.

Echinococcus granulosus Genotypes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The described species *E. granulosus* is subdivided into 10 genotypes (G1-10). Three of them have already obtained the status of an own species.

G4 = *E. equinus* in horses as intermediate hosts.
G5 = *E. ortleppi* in cattle as intermediate hosts.
G7 = *E. canadensis* in pigs as intermediate hosts.

***Echinococcus granulosus* Species Descriptions**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Based on molecular data, McManus (2013) proposed new species (see Table 1).

***Echinococcus granulosus* Species Descriptions, Table 1**

<i>Echinococcus</i> species	Intermediate hosts	Known final hosts
<i>E. canadensis</i>	Camels, goats, sheep, cattle, pigs, boars, beavers	Dogs
<i>E. equinus</i>	Horses, equids	Dogs
<i>E. felidis</i>	Zebra, bushpigs, hogs, buffaloes, antelopes	Lions
<i>E. granulosus</i>	Sheep, cattle, pigs, camels, goats, macropods	Dogs, foxes, dingoes, jackals, hyenas
<i>E. multilocularis</i>	Small mammals, mice, pigs, dogs, monkeys	Foxes, dogs, cats, wolves, raccoon dogs, coyotes
<i>E. oligarthrus</i>	Unknown	Wild felids (jaguars, pumas, ocelots, etc.)
<i>E. ortleppi</i>	Cattle, buffaloes, goat, sheep	Dogs
<i>E. shiquicus</i>	Pikas	Tibetan foxes
<i>E. vogeli</i>	Small mammals, pocus, pagutis	Bush dogs, dogs

Echinococcus oligarthrus

New species from the *E. multilocularis* complex, which may also infect humans. Intermediate hosts are rodents, final hosts are felids in Central and South America.

Echinococcus ortleppi

Cattle strain (G 5) of *E. granulosus*, being infective to humans, occurs in Europe, South Africa, India, Sri Lanka, Russia, South America. Final host is dog.

Echinococcus shiquicus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This newly described *Echinococcus* species is restricted to the Tibetan highlands involving the Tibet fox (*Vulpes ferrilata*) as final host and a peculiar hare (*Ochotona curzoniae*) as intermediate host. It reaches a length of up to 1.7 mm, has only 2–3 segments, possesses 20–23 rostellar hooks, and about 12–20 testes.

Echinococcus Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *echinos* = hedgehog; *kokkos* = spherical; the name refers to appearance of the brood capsule. Latin: *granulosus* = containing granules = tiny slices; *multilocularis* = forming many empty hollows. English: tiny dog dwarf worm.

Geographic Distribution/Epidemiology

E. granulosus occurs worldwide in all countries with sheep farming. *E. multilocularis* occurs from Siberia to West Europe until South France; it is also found in Hokkaido (Japan) and focally in

North America. *E. vogeli* occurs in Uruguay. While worldwide only rather few (several thousands) humans are infected with *E. multilocularis*, hundred thousands of humans become infected by *E. granulosus* in countries with intense sheep farming.

Morphology/Life Cycle

- (a) *E. granulosus* prefers dogs besides foxes as final hosts. The adult worm reaches a length of 2.5–6 mm (Figs. 1, 2, 3, and 4) and possesses mostly only three proglottids, whereby the last one is mostly longer than the whole anterior portion. The scolex of this worm attaches itself at the intestinal wall by help of the four suckers and a rostellum of hooks (consisting of 30–42 small or large hooks that measure either 25–40 μ m or 19–35 μ m). Infected final hosts always contain numerous of these worms. The eggs are of the *Taenia*-type measuring 30–40 μ m in diameter. They contain when being set free from disrupted proglottids already the infectious larva (oncosphere). Different strains of *E. granulosus* prefer different intermediate hosts (Fig. 5) and have developed slight differences in the appearance of the terminal proglottids. If intermediate hosts (sheep, cattle, other ruminants) or humans ingest infectious oncosphere larvae inside eggs being excreted by final hosts (dogs, foxes; Fig. 1), formation of so-called hydatids occurs, wherein numerous protoscolices (young tape worms) are formed asexually (► [metagenesis](#)) within brood capsules (Figs. 6, 7, 13, 15).
- (b) *E. multilocularis*: This worm prefers as final host foxes besides dogs, and in rare cases cats are also infected (Figs. 2, 8, 9). As adult worm it reaches in general a length of 1.5–3 mm. The last proglottid, which contains the infectious eggs, does mostly not surmount the common length of the anterior 4–5 ones (Fig. 2), when being disrupted and discharged within the feces. The scolex is armed by 4 suckers and by a rostellum of 26–36 hooks, which includes larger ones (25–29 μ m) as well as smaller

Echinococcus Species, Fig. 1 Life cycle of *Echinococcus* species. Life cycles of *Echinococcus granulosus* (1–8) and *E. multilocularis* (1.1–8.1). 1, 1.1 Final hosts may be dog, cat, or fox with clear, species-specific preference. 2–3.1 Adult worms, which live in the small intestine of the final host, may be differentiated according to the size of their terminal proglottids (P) and shape of uterus (UE) and according to the size of rostellar hooks. 4, 4.1 Eggs containing an infectious oncosphere larva are released from the detached drying proglottid in the feces of the host; eggs are indistinguishable from those of *Taenia* species. 5. 5–1 Eggs are orally ingested by intermediate hosts or man with contaminated food. 6, 6.1 Inside the intestine of the intermediate hosts (including man), the oncosphere hatches, enters the wall, and may migrate (via

blood) to many organs. Cysts are formed mostly in the liver and lung. In *E. granulosus* large unilocular ► [hydatids](#) occur, which are filled with fluid (containing thousands of protoscolices), whereas in *E. multilocularis* a tubular system infiltrates the whole organ (giving rise to alveolar aspects in sections). 7 – 8.1 In brood capsules of both cyst types, protoscolices are formed, which may become evaginated (8) even inside their cysts. Evaginated or not, protoscolices are fully capable of infecting final hosts when they feed on infected organs of intermediate hosts (BC = in brood capsule; EB = ► [embryophore](#) of the egg; EX = excretory vessels; GP = genital pore; H = hydatid; HO = hooks of oncosphere; IR = invaginated rostellar hooks; P = proglottid; RH = rostellar hooks; SU = sucker; TU = tubular system; UE = uterus containing eggs)

Echinococcus Species, Fig. 2 Scanning electron micrograph of adult worms of *E. granulosus* (left) and *E. multilocularis*

Echinococcus Species, Fig. 3 Light micrograph of a stained adult worm of *E. granulosus* showing the typical large last proglottids

ones (19–24 μm). Intermediate hosts are mainly rodents (e.g., mice, rats; Fig. 1). In these hosts (but unfortunately also in humans), a so-called alveolar cyst is developed from each ingested egg of this tapeworm. Inside this cyst (with hollow channels and cancer-like growing undifferentiated cells; Figs. 10, 11, 12, 15), finally young tapeworms (protoscolices) are developed which become sexually mature, if they are ingested by the final host (fox, dog, cat).

- (c) ***Echinococcus vogeli***: This species parasitizes as adult worms in forest dogs (e.g., *Speothos venaticus*) in Central and South America reaching a size of 2.2–2.9 mm. Intermediate hosts are rodents (*Agoutis* species), cotton rats (*Pacas* species), and occasionally humans. In the case of humans, a polycystic echinococcosis is introduced.

- (d) ***Echinococcus shiguicus*** occurs in so-called Tibet foxes (*Vulpes ferrilata*) in Tibet. Intermediate hosts are pika (*Ochotona curzoniae*).
- (e) ***Echinococcus oligarthrus*** occurs in wild cats (jaguar, puma) in Central and South America. Intermediate hosts are cotton rats.

Symptoms of Disease (Echinococcosis)

Final hosts mostly show only low-graded symptoms, if at all, so that the danger of human infections remains mostly hidden. Only in cases with huge numbers of worms all three species induce catarrhalis or hemorrhagic reactions. In contrast to these low-graded symptoms in final hosts, intermediate hosts are severely affected and infections may also end fatal, since the liver, brain, lung, and other organs may become completely destroyed.

Fig. 6 Macrophoto of three closely attached hydatid bladders of *E. granulosus* from the uterus of a woman

E

Echinococcus Species,

Fig. 7 Macrophoto of sheep liver containing many hydatids of *E. granulosus*

**Diagnosis**

In infected humans it is needed to detect and define the different cyst types in the infected tissues, since only the hydatids (formed by *E. granulosus*) can be removed by surgical processes. The detection of all cyst types can be done by computer tomography or sonography or even

by help of X-rays. Serological methods (ELISA, PCR) allow a species determination, which is important, since small cysts may appear rather similar in optic methods. Other serological methods are only successful in 50–60% of lung echinococcosis. The relevant titer in IIFT is 1:320, in IHAT 1:16,000, while ELISA is positive at values 1:80.

Echinococcus Species, Fig. 8 Scanning electron micrograph of the scolex of *E. multilocularis*

Infection

Oral uptake of eggs from feces of infected final hosts.

Prophylaxis

Avoid of contact with foxes or foreign stray cats and dogs. Family dogs and cats should be treated with anthelmintics in intervals of about 2 months, in case feed on mice which might be intermediate hosts.

Incubation Period

In humans it takes often years, until tissue cysts are grown up. In final hosts incubation periods are short: 4–5 weeks.

Prepatent Period

In **final hosts**, depending on the species, the prepatent period of *E. multilocularis* is about

Echinococcus Species, Fig. 9 Light micrograph of a longitudinal section through an adult worm of *E. multilocularis* inside the intestinal wall of a fox

36–38 days and *E. granulosus*, 35–42 days; in **humans**, at least 1–2 years.

Patency

In **final hosts**, the patency of *E. granulosus* is ~7 months and *E. multilocularis*, 5–6 months; in **humans**, several years.

Therapy

E. granulosus cysts in **humans** can be surgically removed. *E. multilocularis* cysts are mostly inoperable, and thus the patient must be treated for the rest of his/her life by albendazole (12–15 mg/kg bodyweight/daily) or mebendazole (50–60 mg/kg bodyweight/daily). After 2 years it should be tested, whether parasites have been killed, otherwise treatment has to go on.

Dogs and cats can rather easily be dewormed by application of praziquantel (1×5 mg/kg bodyweight). Their feces should be thoroughly discharged.

Echinococcus vogeli

New species from the *E. multilocularis* complex, occurs in Central and South America. Rodents are intermediate hosts; humans may be infected. Final hosts are bush dogs.

Echinolaelaps

Genus of rat ► [mites](#).

Echinoparyphium recurvatum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This trematode belongs to the group of *Echinostoma* species and is characterized by

45 spikes at its bulbous collar. It reaches a length of 5 mm and parasitizes inside the intestine of waterbirds. The eggs measure $110 \times 80 \mu\text{m}$.

Therapy

See *Echinostoma* species.

Echinophthiriidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *echinos* = hedgehog; *phteir* = louse. This term describes a family of the blood sucking lice (► [Anoplura](#)), the members of which have adapted to survive on pinnipeds, which include mammals such as fur seals and sea lions, walruses (Odobenidae) and “true” seals (Phocionidae). The family Echinophthiriidae comprises of 12 species with five genera:

- *Latagophthirus* (on river otters)
- *Proechinophthirus* (on seals and sea lions)
- *Lepidophthirus* (on true seals)
- *Echinophthirus* (on true seals)
- *Antarctophthirus* (on sea lions, walruses, true seals)

Echinostoma ilocanum

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *echinos* = hedgehog. Latin: *stoma* = mouth, spherical opening; *canis* = dog. English: spinal collar fluke.

Geographic Distribution/Epidemiology

In countries in Southeast Asia such as the Philippines, Japan, and India, several hundred thousand humans are infected (probably more, since symptoms are mostly low graded).

Morphology/Life Cycle

The trematode species *Echinostoma ilocanum* reaches a size of 7×1.5 mm and parasitizes in the small intestine of humans and of many mammals (e.g., dogs), but also enters the intestine of birds feeding mussels or snails. This species is characterized by an anterior collar, which bears 49–51 spikes (Figs. 1 and 2). Since these worms suck blood after they had destroyed blood vessels of the intestinal wall, they appear reddish. The excreted eggs are unembryonated, measure $90\text{--}115 \times 60\text{--}70$ μm , and are found in the feces of their hosts. The formation of the miracidium starts as soon as these eggs become covered by water. Finally the miracidium larva hatches from the egg and penetrates into water snails (*Gyraulus*, *Hippeutis* species), wherein finally cercariae are produced. The second intermediate hosts are again water snails (often *Pila*, *Lymnaea*, or *Viviparus* species, respectively, and some species of mussels (e.g., *Corbicula* species)). If final hosts (inclusive humans) ingest these metacercariae in

***Echinostoma ilocanum*, Fig. 1** Light micrograph of the anterior end (bulbus) being armed by specific numbers of spines, which are used to scratch at the intestinal wall and thus to introduce bleeding. The blood is then sucked in

raw snails or mussels, development of the adult starts in their small intestine.

Symptoms of Disease (*Echinostomiasis*)

In case of infections with numerous worms, their hooks damage the intestinal wall which leads to diarrheas combined with abdominal pain. Important dehydration may occur leading to headache. Symptoms of intoxication may occur, too. Blood loss may introduce anemic symptoms. Furthermore a considerable eosinophilia is one of the late symptoms.

Diagnosis

Microscopical demonstration of the rather large eggs by the help of the ► [sedimentation](#) method.

Infection

Oral uptake of metacercariae in raw mussels or snails. Therefore many reserve hosts

***Echinostoma ilocanum*,**

Fig. 2 Diagrammatic representation of life cycle of *Echinostoma ilocanum*.

(A) **Final host (man):** (1) Sexually mature intestinal fluke. (2) Freshly laid egg. (3) Egg with miracidium.

Echinostoma revolutum, Fig. 1 Light microscopic photo of a non-embryonated egg of *E. revolutum*

Echinostoma revolutum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *stoma* = mouth. Latin: *echinatus* = with spines; *revolvere* = turning around.

Geographic Distribution/Epidemiology

Worldwide, occasionally epidemics occur in mass animal farms.

Morphology/Life Cycle

The adults of trematode species *Echinostoma revolutum* reach a length of about 2 cm and are characterized by 37 spikes at their anterior bulbous. These flukes parasitize mainly in the ceca and in the rectum of water birds and produce 90–130 $\mu\text{m} \times 60\text{--}70 \mu\text{m}$ sized eggs (Fig. 1), which possess an operculum and which are found in the feces in an unembryonated stage (*Echinostoma ilocanum*; see Fig. 2). Inside the egg a miracidium larva is developed within 18–30 days if the eggs are laid into water. After hatching from the eggs the larvae penetrate into

water snails (e.g., *Lymnaea*, *Planorbis*). The therein produced cercariae enter tadpoles, mussels, and snails and become finally transformed into metacercariae. If final hosts (inclusive humans) ingest such second intermediate hosts, adult worm may develop within their intestines.

Symptoms of Disease (Echinostomiasis)

Infections with a low number of worms remain often hidden; however, huge numbers of worms may lead to bloody diarrheas, loss of weight or in case of birds often to death due to bleeding lesion.

Diagnosis

Microscopical determination of the typical eggs (Fig. 2) by help of the ► [sedimentation](#) method.

Infection

Oral uptake of infected snails, mussels, tadpoles.

Prophylaxis

Humans should avoid eating raw snails and mussels.

Prophylaxis

Avoid eating raw snails and clams.

Therapy

Treatment see Trematodocical Drugs.

Eckert's Method

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes a method of the German parasitologist Johannes Eckert (late chairman of Veterinarian Parasitology in Zurich, Switzerland) to cultivate and obtain worm larvae from animal feces. The procedure takes the following steps:

1. Ten grams of feces is mixed intensively with sawdust in a glass vessel.
2. The glass vessel is closed with a cap and stored in an incubator at 24–28 °C for 10–12 days.
3. The cover is removed daily for 30 min, and the mixed material is slightly moistened before closing the vessel.
4. After 10–12 days the incubated material is pressed, and the vessel is completely filled with water.
5. The vessel is covered with a petri dish and placed top down under for 12–14 h.

Then the larvae, which have developed inside the sawdust-fecal mixture, can be obtained by the help of a pipette along the border between the glass vessel and petri dish and determined light microscopically.

Eclosion

Shedding of pupal exuviae in insects (e.g., in *Nasonia* spp. among Ichneumonoidea).

Echinuria uncinata

Stomach worms of ducks and geese
(male = 10 mm, female = 19 mm).

Ecoparasitological Aspects

Such factors have been taken into account when explaining fluctuations of population densities in

the field. For example, some trematode developmental stages limit the number of their hosts in a given ecosystem.

Ecosystems and Parasitism

The role of parasites can be extremely important in the equilibrium of ecosystems because a change in the impact of parasites, due, for instance, to an alteration of climatic or other conditions, may have unexpected and profound consequences.

Although the relationship between parasites and ecosystems is still little documented, the following examples illustrate the mechanisms by which apparently little parasitological causes can have dramatic effects.

Lindström et al. have shown that an epizooty of ► [sarcoptic mange](#), which decimated the populations of red foxes in Scandinavia, has favoured the demographic growth of several small mammals which were the prey of the foxes; some of these mammals rapidly tended to pullulate, destroying certain plants, and finally modifying the landscape.

Holmes has drawn attention to the importance of ecosystem shrinking, due for instance to agriculture, deforestation, construction of highways, etc. In the new landscapes created by such fragmentation, there is an intrication of different faunas which lead some parasites to attack unusual host species, which have often limited innate defenses against them. Holmes mention the case of a Californian bird parasite, the brown-headed cowbird, *Molothrus ater*, which, in shrinking ecosystems, tend to lay its eggs in the nests of passerine it had never parasitized before. These new bird hosts are incapable of rejecting the eggs of the parasite, whereas the “usual hosts” identify and reject “alien” eggs to a certain extent. Some passerine species seem to have been threatened so much with extinction that scientific meetings have been organized to try to stop the process.

Parasites intervene also in the structure of biodiversity (composition of faunas) by interfering with competition processes (► [Host Demography](#)) and significantly alter the structure and functioning of ecosystems, as recently demonstrated by Lafferty, Dobson, and Kuris.

Ecotope

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes a rather small, uniform environment, within which a small number of organisms intensively interact (e.g., fish, parasites, fungi in muddy shores of lakes, etc.).

Ectoparasites: New Approaches

Biological Control

The control of parasitic flies by biological methods has become a viable method in some specific cases.

The release of large numbers of genetically manipulated (either by irradiation of genetic transformation) sterile or “less fit” flies into the environment has led to the elimination of the screwworm fly (*Chrysomya*) in the USA. This control method has also been applied to blowflies (*Lucilia cuprina*) and is part of a long-term

strategy to control sheep blowfly. In Australia the use of natural pesticides as another “environmentally friendly” biological pesticide is an area where innovative applications are expected to investigate these opportunities for future products. First biopesticides such as ► [Bacillus thuringiensis](#) and *Metarhizium anisopliae*-based products reached the crop protection market in the late 1980s. But both approaches are still in their infancy in the animal health sector, since due to their high specificity they were suitable for combating only few fly species and never reached broad regional application.

Vaccination

The growing problems of resistance and persistence of residues in meat and milk have created a renewed interest in antiparasitic vaccines.

It has been known for a long time that certain arthropods stimulate an immune response in infested animals. Apart from two x-irradiated worm vaccines there were no significant parasite immunologicals available until the late 1980s. The discovery and improvement of recombinant DNA technology has created hope that the capability of expressing specific, protective antigens not only against endoparasites, but also parasitic arthropods will lead to new innovative vaccines.

This field is potentially very interesting, but both the life cycle of the arthropods targeted and the limited range of cross-reactivity between related strains as well as the technology involved is highly complex.

Table 1 shows where certain activities have been focused, but considering market success as final proof, none of these vaccines achieved a significant share either in treatment numbers or in sales, when compared even to “weak” chemicals.

One fundamental problem with vaccine research is the identification of the protective antigens. For complex organisms, such as arthropods, this makes the isolation of useful antigens very difficult, but in the future due to improvements in DNA technology, this technique may start to have a significant impact on treatment against arthropods.

Ectoparasites: New Approaches, Table 1 Vaccine approaches against ectoparasites

Target parasite	Approach/status
Warble fly/Cattle grub (<i>Hypoderma bovis</i> , <i>Hypoderma lineatum</i>)	The most advanced immunization trials against myiasis have been performed against <i>Hypoderma</i> . Some protection against later infections was observed in the field. More detailed investigation revealed, that particularly first-instar larvae were sensitive. Studies on the protein composition of <i>H. lineatum</i> larvae which might induce protection showed that so-called hypodermins were potentially useful antigens. Hypodermins (type A,B,C) are serine proteinases which are of importance for larval tissue migration. Vaccination with hypodermin antigens resulted in up to 90 % protection (hypodermin A) and some degree of cross-protection between <i>H. lineatum</i> and <i>H. bovis</i> . So far, as with almost all insect ectoparasite vaccination approaches no field vaccine is currently available
One-host ticks (<i>Boophilus microplus</i>)	Tickgard is a vaccine based on a recombinant hidden antigen, membrane-bound glycoprotein Bm86. The vaccine has achieved some success in Australia against <i>B. microplus</i> , particularly in dairy herds. Vaccination results in some mortality in engorging ticks and to significant tick mortality between full engorgement and egg laying. The discovery of these specific tick antigens has opened the possibility of identifying similar proteins in other <i>B. microplus</i> strains and probably in other tick species as well. Other interesting antigens (Bm91, Qu13) have been identified, but so far none appear to be as effective as Bm86. Since the current vaccine is particularly effective in reducing the reproductive capacity in engorging female ticks, the continual introduction of ticks or tick-infested animals into a vaccinated herd significantly interferes with a successful strategic vaccination. Highest performance of the vaccination was observed when vaccinated animals were isolated from continual reinfection
Blowfly strike (<i>Lucilia cuprina</i>)	For the time being it is believed that binding of antibodies to the respective antigens leads to a layer covering the peritrophic membrane (PM) which results in restricted permeability of <i>L. cuprina</i> larvae fed on vaccinated sheep. Peritrophins of different molecular weight have been identified, which led to starvation through the binding of antibodies to these PM-associated antigens. Despite substantial progress in comparison to the past a useful vaccine is not available so far
Fleas (<i>Ctenocephalides felis</i>)	Hyperimmunized rabbit antisera against concealed antigens of flea midgut, the major digestive organ, revealed when fed in an artificial feeding system, significant decrease of survival rate and egg production of <i>C. felis</i> fleas. These preliminary studies demonstrated the feasibility of vaccination against cat fleas. Similar results were obtained following the vaccination of dogs with subsequent challenge. In these preliminary studies statistically significant reduction of about 25 % regarding flea numbers remaining on the animal in comparison to control animals was observed. Despite the fact that at least partially protective antigens have been identified, so far no recombinant vaccine displaying substantial field success is available
Salmon louse (<i>Lepeophtheirus salmonis</i>)	Vaccination might be a valuable method to control copepod infestation which are major parasites of farmed salmonids. Antibodies were raised against various <i>L. salmonis</i> antigens. When assessed with immunohistochemical methods gut and ovarian hidden antigens were recognized by respective Mabs ^a . Then MABs were used to screen <i>L. salmonis</i> DNA libraries in order to identify DNA fragment coding, for proteins which might be useful as a basis for recombinant vaccines

^aMonoclonal antibodies

Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission

Andreas Turberg
Bayer Healthcare AG, Bayer Animal Health
GmbH, GDD-AH-PARA-APR, Monheim,
Germany

Mode of Action

See Fig. 1.

Structures

See Fig. 2.

Organohalogenides

Important Compounds

Bromopropylate

General Information

Bromopropylate (phenisobromolate) [isopropyl 4,4'-dibromobenzilate] acts similar to organophosphorus or carbamate compounds and is a weak inhibitor of the insect acetylcholinesterase. Additionally, the compound has a measurable effect on voltage-sensitive sodium channels of insect neurones. Despite its structural similarity with ► **DDT** (dichlorodiphenyltrichloroethane) or methoxychlor, this effect is not comparable to that of DDT. Bromopropylate is a nonsystemic acaricide with contact action and long residual activity. The compound is used against ectoparasites for diagnosis and control of mite infestations in bees. LD₅₀ acute oral toxicity for rats is >5,000 mg/kg (acute percutaneous LD₅₀ > 4,000 mg/kg). The compound is toxic to fish. In mammals, bromopropylate is rapidly and efficiently eliminated. Metabolism occurs mainly by cleavage of the isopropyl ester and to a minor extent by oxidation. Metabolites of the oxidation products are 3-hydroxybenzilate and conjugates.

Resistance

Resistance of ectoparasites against bromopropylate is based on sequestration by enhanced hydrolytic activities (carboxylesterases) as well as on oxidation by monooxygenases. Bromopropylate-resistant *Varroa* ► **mites** have not yet been reported.

Organophosphorus Compounds

Important Compound Groups

Organophosphates, organophosphonates, monothiophosphates, dithiophosphates.

General Information

Insecticidal organophosphorus compounds were synthesized for the first time by G. Schrader nearly 60 years ago. Organophosphates are inhibitors of hydrolases, e.g., carboxylesterases (aliesterase) and acetylcholinesterases. Several different isoforms of acetylcholinesterases have been identified in the insect central nervous systems which are differentially inhibited by organophosphates. The reaction mechanism of organophosphates with acetylcholinesterase resembles that of the endogenous substrate acetylcholine. The hydroxyl group of a specific serine residue of the acetylcholinesterase is acetylated by acetylcholine, phosphorylated by organophosphates, and carbamylated by carbamates. This indicates a competitive mode of action. Since the inhibition constant of organophosphate compounds is small, the compounds occupy the active site, thus reducing hydrolysis of acetylcholine in the synaptic cleft. Neuronal transmission is influenced by stimulation of cholinergic synapses followed by depression and paralysis.

Resistance

Tolerance or resistance occurs against all of the organophosphates currently on the market. However, resistance is still restricted to limited areas and specific ectoparasites. Reported resistance factors for ectoparasites like cattle tick or cat flea are in the range of 1.5-fold (which in fact should be called biological variability or at the most tolerance) to >100-fold. Organophosphate-resistant tick strains of the southern cattle tick *Rhipicephalus*

Ectoparasiticides: Agonists and Antagonists of Cholinergic Transmission, Fig. 1 Model of the action of drugs interfering with acetylcholine mediated neurotransmission

(*Boophilus microplus*) have been identified in Australia, South Africa, Argentina, Brazil, Colombia, Ecuador, Costa Rica, and Uruguay. Laboratory tests demonstrated different degrees of resistance from tolerance (1- to 4-fold reduced susceptibility) via slightly resistant (5- to 20-fold) to resistant strains (>20-fold). Field testing revealed that organophosphate resistance was widespread among Australian strains of *R. (B.) microplus*. Several organophosphate and carbamate insecticides have been tested against a resistant flea strain (*Ctenocephalides felis*) from Florida and compared to a susceptible strain. Malathion (dithiophosphates; see Fig. 3) and carbaryl (carbamates) have been used in flea control at the Florida strain origin for about 30 years. The results indicated a <10-fold tolerance

for organophosphates other than malathion which had a 25-fold higher LC_{50} than with susceptible control ► [fleas](#). Under laboratory conditions, a 12-fold resistance against malathion has been observed upon continuous selection of adult fleas for eight generations. In an organophosphate-resistant field strain of the cat flea *C. felis*, two possible resistance mechanisms have been identified: detoxification by glutathione S-transferases and target site insensitivity of acetylcholinesterase. Hence, it is speculated that rotation with carbamate insecticides would not control this flea strain. Resistant strains of the housefly showed reduced ► [cuticle](#) adsorption of organophosphates, reduced formation of biologically highly active oxon derivatives, accelerated formation of phosphates from

Fig. 3 Enzymes involved
in detoxification of
malathion

thiophosphate derivatives, and reduced sensitivity of cholinesterases. For decades, organophosphates have been the only products for sheep treatment against blowfly strike and ► [lice](#) in Australia. Resistance against, e.g., diazinon was detectable in 1965 in 20 % of the adult blowflies at a low level. In 1970 about 95 % of the flies were diazinon resistant. In 1995 this value had stabilized at about 97 %. In the case of blowfly control, the occurrence of resistance did not mean a total control failure. For diazinon, the protection period was reduced from about 12 weeks to 4–6 weeks. The actual resistance factors for more than hundred field populations of blowfly are in the range between 2-fold (tolerance) and 42-fold in laboratory trials predominantly concentrating at the higher range. For diazinon (monothiophosphates) and fenthion, a delayed cuticular adsorption was observed with resistant housefly strains. For most ectoparasites resistant or tolerant against organophosphates, one or more of the following resistance mechanisms have been identified (see Fig. 3): hydrolysis by carboxylesterases (alisterases), thus quenching the inhibitor, oxidation by microsomal enzymes (e.g., cytochrome P450 monooxygenases), dealkylation by glutathione S-transferases, and

target enzyme insensitivity toward organophosphates. By molecular biology techniques, additional resistance mechanisms have been demonstrated, e.g., multiple alleles of cholinesterases with altered specificity and enhanced enzyme expression levels.

Organophosphorus compounds play an ongoing important role in the treatment of ectoparasitic diseases. Resistance has been encountered with synergistic additives inhibiting metabolic enzyme activities, e.g., piperonyl butoxide (PBO) as mixed-function oxidase inhibitor, S,S,S-tributyl phosphorotrithioate (TBPT) and triphenyl phosphate (TPP) as inhibitors of detoxifying esterases, and diethyl maleate (DEM) as an inhibitor of glutathione S-transferase-mediated detoxification.

Organophosphates and Organophosphonates

Important Compounds

Chlorfenvinphos, dichlorvos (DDVP), dicrotophos, heptenophos, naled, tetrachlorvinphos (CVMP), trichlorfon/metrifonate.

General Information

Chlorfenvinphos is a broad-spectrum insecticide and acaricide with contact and stomach action. It has a long residual activity and requires withdrawal periods of 3–21 days (depending on the respective formulation) for meat-producing animals treated with the compound. It is used against blowfly strike and also for control of ► [ticks](#), lice, ► [keds](#), and screw worm. Chlorfenvinphos shows fish toxicity and only slight bee toxicity. Among the organophosphorus compounds, it shows a relatively high acute oral toxicity against rats (9.6–39 mg/kg LD₅₀). On the other hand, the compound is metabolized quickly in mammals by de-esterification to give 2-chloro-1-(2,4-dichlorophenyl)vinyl ethyl hydrogen phosphate. Excretion products are glucuronic acid conjugate and monohydrolyzed metabolites. Dichlorvos (DDVP) is a rapid knockdown insecticide and acaricide with respiratory, contact, and stomach action which rapidly decomposes in soil. Besides applications on pets and cattle, dichlorvos has been used also against ectoparasites on salmon and trout. Because of its ability to act systemically, dichlorvos is also used in animal treatment against ► [nematodes](#), ► [trematodes](#), or cestodes. It is metabolized in mammals by hydrolysis and O-methylation. Acute oral toxicity for rats is LC₅₀ mg/kg (LD₅₀, acute percutaneous 90 mg/kg). High toxicity to birds and bees has been observed. The metabolism of DDVP in mammals occurs rapidly with a half-life of 25 min by hydrolysis and O-methylation in the liver. It is nonpersistent in the environment. Dicrotophos is a systemic insecticide and acaricide with contact and stomach action and moderate persistence. Acute oral toxicity for rats is 17–22 mg/kg (LD₅₀, acute percutaneous 110–180 mg/kg). It is very toxic to honey bees but due to rapid decline of compound on surfaces with little effect in practice. Dicrotophos is completely metabolized and eliminated in rats and dogs a few days after oral administration. Heptenophos represents a systemic insecticide with contact, stomach, and respiratory action with fast initial activity and short residual effect. Acute oral toxicity for rats is 96–121 mg/kg (LD₅₀). In mammals, the compound is excreted

to 96 % within 6 days in metabolized form in urine and feces. Naled is a fast-acting nonsystemic insecticide and acaricide with contact, stomach, and some respiratory action. The biological activity may be due to in vivo debromination forming dichlorvos (q.v.). The compound is used against ► [hygiene](#) pests and in animal houses and against ticks and fleas on pets. Acute oral toxicity for rats is 430 mg/kg (LD₅₀). The compound causes skin irritation and eye burns on rabbits at an acute percutaneous LD₅₀ of 1100 mg/kg. Tetrachlorvinphos (CVMP) is a nonsystemic insecticide and acaricide with contact and stomach action. The compound is active against flies, fleas, ticks, and lice on pets and cattle, on swine and poultry, and in animal houses. LD₅₀ acute oral toxicity for rats is 4,000–5,000 mg/kg. Low toxicity for birds and high toxicity for bees have been observed. In mammals, tetrachlorvinphos is metabolized and eliminated quickly. Major metabolites found in the urine of rats and dogs were glucuronic acid derivatives, mainly 2,4,5-trichlorophenyllethandiol glucuronide, 2,3,5-trichloromandelic acid, and 2-chloro-1-(2,4,5-trichlorophenyl)-vinyl methyl hydrogen phosphate. Trichlorfon is an organophosphonate insecticide with contact and stomach action. It is used to control fleas, flies, keds, lice, warble flies, and ► [mange mites](#) on farm animals. It is also active against a variety of fish ectoparasites. Acute oral toxicity for rats is 560–630 mg/kg (LD₅₀; acute percutaneous >2,000 mg/kg). Toxicity to fish and bees is moderate. In mammals, the compound is rapidly degraded in the blood. Trichlorfon excretion in the urine is complete within 6 h. Major metabolites are dimethylphosphoric acid, monomethylphosphoric acid, and dichloroacetic acid. As metrifonate the compound is used as an anthelmintic against nematodes, trematodes, or cestodes.

Monothiophosphates

Important Compounds

Azamethiphos, chlorpyrifos, coumaphos, cythioate, diazinon (dimpylate), famphur (famophos), fenitrothion, fenthion (MPP), iodofenphos, phoxim, propetamphos, temephos.

General Information

Azamethiphos is an insecticide and acaricide with predominantly contact action that shows quick knockdown and good residual activity. The acute oral toxicity for rats is low (LD_{50} 1,180 mg/kg; percutaneous $>2,150$ mg/kg), but bee toxicity has been observed and it was classified as highly toxic to fish (rainbow trout). However, the compound has been tested against fish lice on salmon with positive results (efficacy at 0.01 ppm) and good tolerance by salmon. Major metabolite in mammals is the glucuronic acid conjugate of 1-amino-3-hydroxy-5-chloro-pyridine. Azamethiphos is mainly used for control of public hygiene pests and insect pests in animal houses. Chlorpyrifos is a nonsystemic compound with contact, stomach, and respiratory action and efficacy against fleas, ticks, and sarcoptic mite. Acute oral toxicity for rats is 135–163 mg/kg (LD_{50} ; acute percutaneous $>2,000$ mg/kg) but it shows bee toxicity and high fish toxicity (0.003 mg/l LC_{50} for rainbow trout). Its slow degradation in soil to 3,5,6-trichloro-pyridin-2-ol with a half-life of 80–100 days is responsible for the long persistence in environment. Metabolism in mammals following oral administration is rapid and leads to the same major metabolite which is excreted via urine. Coumaphos is a broad-spectrum insecticide and acaricide with predominantly contact action. Coumaphos (as 25 % WP) has been an approved Animal and Plant Health Inspection Service United States Department of Agriculture (APHIS-USDA)-permitted pesticide for treatment of screw worms, ► [scabies](#), and ticks in federal eradication programs. Systemic action in the host animal is directed against warble flies. Withdrawal periods for meat are 15 days to 3 weeks depending on formulation. LD_{50} acute oral toxicity in rats is 16–41 mg/kg (LD_{50} percutaneous 860 mg/kg). Because of its relatively low toxicity for bees, it is also used as a miticide against *Varroa* mites in beehives. Because of its ability to break existing resistance, interest in the ► [varroaosis](#), treatment with coumaphos has recently grown especially in the southern part of the United States. Coumaphos is also used in animal treatment against nematodes, trematodes, or cestodes. Cythioate is rapidly absorbed from

the gastrointestinal tract after oral dosing with maximum drug effect for up to 8 h after administration. Fleas and other ectoparasites like ticks and mange mites are killed when they ingest the body fluids of the host. LD_{50} acute oral toxicity for rats is 107–246 mg/kg. The compound is rapidly eliminated from the body. Diazinon (dimpylate) is a broad-spectrum insecticide and acaricide with contact, stomach, and respiratory action. Withdrawal times for meat range from 3 to 14 days depending on formulation and host species. Acute oral toxicity for rats has LD_{50} from 240 to 480 mg/kg body weight. The compound shows a pronounced bee toxicity. The bird toxicity is impaired with bird-repelling properties. Major metabolites in mammals are diethyl thiophosphate and diethyl phosphate. Famphur is used as ectoparasiticide against horn flies, grubs, and lice in cattle and reindeer. LD_{50} acute oral toxicity for rats is 27–62 mg/kg for rats. Fenitrothion is a nonsystemic insecticide with contact and stomach action and ectoparasitidal activity against fleas. It is used as a public health insecticide and for control of flies in animal houses. LD_{50} acute oral toxicity for rats is between 250 and 800 mg/kg (acute percutaneous LD_{50} 890 mg/kg). Fenitrothion is rapidly excreted in the urine and feces (90 % after three days in rats). Major metabolites are dimethylfenitrooxon and 3-methyl-4-nitrophenol. Fenthion is a systemic broad-spectrum insecticide with contact, stomach, and respiratory action against a variety of ectoparasitic insects and hygiene pests. Acute oral toxicity for rats is 250 mg/kg (LD_{50} ; acute percutaneous 700 mg/kg). After oral administration, the compound is eliminated in mammals mainly in the form of hydrolysis products in the urine. The major metabolites are fenthion sulfoxide, fenthion sulfone, and their oxygen analogues. These metabolites are further hydrolyzed to the corresponding phenols. Iodofenphos is a nonsystemic insecticide and acaricide with contact and stomach action used as a premise ectoparasiticide in poultry houses. It shows low toxicity to mammals and is nontoxic for birds. Phoxim is a broad-spectrum insecticide and acaricide with contact and stomach action and a short-term activity. It controls mange mites, lice, keds, flies, fleas, and fly larvae. Acute oral toxicity

for rats is 1,976–2,170 mg/kg (LD₅₀; acute percutaneous >1,000 mg/kg). The compound is toxic for fish and bees (contact and respiratory action). In mammals, it is rapidly metabolized to diethylphosphoric acid and desethylphoxim. The nitrile is metabolized to phoxim carboxylic acid and metabolism of the oxon is also unusually fast. As much as 97 % is secreted within 24 h in the urine and feces. Propetamphos is an insecticide and acaricide with contact and stomach action and long residual activity. Acute oral toxicity for rats is 60–119 mg/kg (LD₅₀; acute percutaneous 2,825 mg/kg for male rats). In mammals, propetamphos is completely metabolized and rapidly excreted mainly via urine and exhaled air. It is detoxified through hydrolytic reactions involving the phosphorus and carboxylic ester bonds followed by ► [conjugation](#) and through oxidation processes leading ultimately to CO₂. Temephos, a nonsystemic insecticide, is used in mosquito larvae control and for treatment of pets against fleas and treatment of humans against lice. The compound shows a low toxicity against mammals (LD₅₀ acute oral toxicity for rats 4,204–>10,000 mg/kg; LD₅₀ acute percutaneous toxicity for rats >4,000 mg/kg), birds, and fish but is highly toxic to bees. In mammals, temephos is mainly eliminated unchanged in the urine and feces.

Dithiophosphates

Important Compounds

Dimethoate, ethion (diethion), malathion, phosmet (PMP, phtalofos).

General Information

Dimethoate is a fast-acting insecticide and acaricide which quickly penetrates the insect cuticle. High initial penetration rate and slow detoxification rate have been observed with the housefly (*Musca domestica*). The oxon compound shows highest insecticidal activity but is more toxic to mammals. Acute oral LD₅₀ of dimethoate for rats is 250 mg/kg; acute oral LD₅₀ of the dimethoxon is 30 mg/kg. Dimethoate is toxic to bees, fish, and arthropod aquatic organisms. Ethion is a nonsystemic acaricide with predominantly

contact action. Only combinations with pyrethroids (deltamethrin, permethrin) or other organophosphorus compounds (dichlorvos) are marketed. Acute oral toxicity for rats is 208 mg/kg (LD₅₀). The compound is toxic to fish and bees. Malathion is a nonsystemic pro-insecticide and acaricide with contact, stomach, and respiratory action. The compound is activated by metabolic desulfuration to the corresponding oxon. It is extensively used for ► [vector control](#) in public health and against ectoparasites of cattle, poultry, dogs, and cats. Malathion is also active against human head and body lice. The lice and their eggs are killed quickly upon treatment with 0.003 % and 0.06 % malathion in acetone. Acute oral toxicity for rats is 1,375–2,800 mg/kg. Malathion shows low toxicity to birds and is toxic for fish and bees. In mammals, the major part of the dose is excreted in the urine and feces 24 h after oral administration. Microsomal liver enzymes start detoxification by formation of malaoxon which is subsequently hydrolyzed by carboxylesterases. Phosmet is a nonsystemic insecticide and acaricide with predominantly contact action. Phosmet controls lice, horn flies, mange mites, and ticks. The compound has also been formulated to act systemically against warble fly larvae and mange mites. Acute oral toxicity for rats is 113–160 mg/kg (LD₅₀). It is toxic to fish and bees. In mammals, it is metabolized rapidly to phthalamic acid and phthalic acid (and derivatives) which are excreted in the urine.

Resistance

Malathion: Organophosphorus compounds.

Carbamates

Important Compounds

Bendiocarb, carbaryl, methomyl, promacyl, propoxur.

General Information

Insecticidal carbamate compounds are inhibitors of acetylcholinesterases and have been synthesized in 1954 for the first time. The kinetic of

acetylcholinesterase inhibition with carbamate compounds has a half-life of about 20 min for the carbamylated enzyme complex which is more reversible than with organophosphates. The more potent carbamates are structurally closely related to acetylcholine. Their weaker reactivity at the active site is compensated by more pronounced enzyme-binding abilities. The signs of intoxication are similar to those of organophosphates. Stimulation of cholinergic synapses is followed finally by paralysis of the ► [ectoparasite](#).

Bendiocarb is an insecticide with contact and stomach action that gives rapid knockdown and has good residual activity. LD₅₀ of acute oral toxicity in rats is 40–156 mg/kg (LD₅₀; acute percutaneous toxicity 566–800 mg/kg). The compound is toxic to bees and fish. In mammals, bendiocarb is rapidly absorbed after oral administration or inhalation. It is rapidly detoxified and eliminated almost completely after 24 h as sulfate or glucuronide conjugate of 2,2-dimethyl-1,3-benzodioxol-4-ol, its major metabolite. Carbaryl is a widely used insecticide with slightly systemic properties and contact and stomach action. The compound was introduced onto the market in 1956. Due to its relatively low toxicity to mammals, it is used against ectoparasites. It shows weak inhibition of cholinesterase. Acute oral toxicity for rats is 500–850 mg/kg (LD₅₀; acute percutaneous toxicity >4,000 mg/kg). The compound is toxic to adult bees but carbaryl is not transferred to the breed. The compound shows moderate toxicity to fish if applied as aqueous solution. Carbaryl has very low toxicity for birds (LD₅₀ >2,000 mg/kg for young pheasants) and has been developed for treatment of ectoparasitic diseases on poultry and other cage birds. Carbaryl does not accumulate in mammals' body tissues and is rapidly metabolized to nontoxic substances, particularly 1-naphthol. This metabolite and its glucuronic acid conjugate are eliminated in the urine and feces. Methomyl is a mixture of (Z) and (E) isomers, the former predominating. It is a systemic insecticide and acaricide with contact and stomach action. It is used for control of flies in animal houses. Today, direct application is being replaced more and more by bait

formulations, reducing the risk of mammalian intoxication. The acute oral toxicity for rats is 17–24 mg/kg (LD₅₀; acute percutaneous toxicity for rabbits >5,000 mg/kg). Promacyl was used until recently as a special tickicide with contact and stomach action against a variety of tick species on cattle in Australia. Since 1997, the compound has not been produced any more. It has favorable withdrawal periods of 24 h (meat) and no withdrawal period for milk. Acute oral toxicity for rats is 1,220 mg/kg (LD₅₀; acute percutaneous toxicity >4,000 mg/kg). Propoxur is a nonsystemic insecticide with contact and stomach action. It gives rapid knockdown and long residual activity. The compound is active against fleas, ticks, lice, and biting lice in dogs and cats. LD₅₀ acute oral toxicity for rats is 95–104 mg/kg (LD₅₀; acute percutaneous toxicity for male rats is 800–1,000 mg/kg). The compound is highly toxic to adult bees but shows low toxicity for birds. In rats, main metabolites are 2-hydroxyphenyl-N-methylcarbamate and 2-isopropoxyphenol that are rapidly excreted in the urine. The carbamic acid residue is decomposed and carbon dioxide is exhaled.

Resistance

Several different resistance mechanisms have been demonstrated in resistant hygiene pests and ectoparasites. Besides observations of reduced cuticle permeability of carbamates in resistant housefly strains, detoxification through metabolizing enzymes is the dominating mechanism of resistance against carbamates. Other than for organophosphates, carbamate resistance depends more on oxidative metabolism. O-Dealkylation, N-dealkylation, and N-methylhydroxylation and to a lesser extent hydroxylation are responsible for detoxification of carbamates like propoxur or carbaryl. In addition, turnover of these reactions is elevated by factors 2–3 in resistant strains compared to susceptible populations. Furthermore, for carbamate-resistant strains of cattle tick (*Rhipicephalus (Boophilus) microplus*), sheep blowfly (*Lucilia cuprina*), and housefly (*Musca domestica*), cholinesterases insensitive to carbamates have been identified. Carbamate insecticides have been extensively used in flea

treatments in Florida. Several flea strains have been isolated that showed tolerance or resistance to carbamates and to organophosphates. Resistance factors for propoxur, carbaryl, and bendiocarb are 4-, 20-, and 28-fold, respectively. Other authors reported strains of *Rhipicephalus (Boophilus) microplus* being resistant against carbamate ectoparasiticides.

Neonicotinoids

Important Compounds

Imidacloprid, nitenpyram, dinotefuran.

General Information

Nicotine is not registered anymore for use against ectoparasites in countries with high registration standards for reasons of its intrinsic high mammalian toxicity. However, the natural product nicotine guided the discovery of a new class of insecticides. About 2,000 derivatives have been synthesized on the way to a group of 10 candidates with highest insecticidal activity finally leading to the synthesis of imidacloprid. In comparison to nicotine, the compound impairs a 9-fold lower acute mammalian toxicity and an average >900-fold higher insecticidal activity. Available data on the mode of action of neonicotinoids predominantly have been generated with imidacloprid. In general, other neonicotinoids behave similarly. From several studies, it can be concluded that potent insecticidal neonicotinoids are (partial) agonists of the postsynaptic acetylcholine receptors of motoneurons in insects. Imidacloprid induces slow depolarization in cell bodies of motoneurons from cockroach nerve cord preparations which is sensitive to nicotinic antagonists like dihydro- β -erythroidine. Imidacloprid is a more potent agonist than nicotine; however, maximum depolarization is slightly lower than with nicotine. Electrophysiological studies with mammalian nicotinic acetylcholine receptors from rat muscle expressed in *Xenopus* oocytes revealed that imidacloprid acts as a 1,000-fold less potent agonist to mammalian nicotinic receptors compared to the naturally occurring agonist acetylcholine. Additionally, the open state phases are

significantly reduced compared to acetylcholine. Binding studies with insect and mammalian brain tissue incubated with tritiated imidacloprid revealed high-affinity binding sites in insect neuronal tissues but not in the mammalian brain. Hence, the favorable toxicity profile of neonicotinoids is also based on target specificity for the different subtypes of nicotinic acetylcholine receptors present in mammals and insects. Docking and mutagenesis studies revealed putative binding sites in α -1 β -2 nAChR from insects and α -4 β -2 nAChR from rats based on crystal structures from freshwater snail *Lymnaea stagnalis* acetylcholine-binding protein complexed with neonicotinoids. Additional insecticidal benefit results from the reduced positive charge under physiological conditions at the receptor-binding nitrogen of neonicotinoid compared to nicotine alkaloids. The positively charged nicotine alkaloids are barely able to cross the lipophilic cuticle of insects, leading to poor contact activity of nicotine. Neonicotinoids show good and long-term systemic action in plants. They are also quickly distributed in mammals upon oral ingestion. However, this efficacy is a short-term response due to rapid elimination with dramatic loss of efficacy after less than 4 days. Residual activity on animals for at least 4 weeks is achieved only through topical application (e.g., imidacloprid, dinotefuran).

Dinotefuran is the most recent addition to the neonicotinoid family. Instead of a chlorpyridyl or a chlorthiazolyl moiety, a furanyl residue has been introduced. Pharmacology at the nicotinic acetylcholine receptor and biological efficacy are comparable to the other members of the class of neonicotinoids. The compound is being developed for use against fleas on pets. Acute toxicity in rats gave an LD₅₀ of 2,804 and 2,000 mg/kg body weight for male and female, respectively. Acute dermal toxicity is >5,000 mg/kg in rats. The compound shows moderate eye irritation and no skin irritation in rabbits. Dinotefuran is not a skin sensitizer. It is nontoxic to birds and fish, No Observed Adverse Effect Concentration (NOAEC) for *Daphnia magna* is 95 ppm. Dinotefuran is highly toxic to bees. The compound has recently been combined with a

pyrethroid to enhance the antiparasiticide spectrum. Imidacloprid is an insecticide with contact and stomach action introduced in 1992 as a new chemical entity insecticide in crop protection. Four years later, imidacloprid was introduced as the active ingredient of a new and highly effective ectoparasiticide against adult fleas. In topical formulations, imidacloprid has a long residual activity. Recently, a combination of imidacloprid was developed with an endectocide that is used against intestinal parasites including heartworm, against diseases caused by mite infections, as well as against lice and fleas (► [Moxidectin](#)). The compound has also been combined with a permethrin to enhance the antiparasiticide spectrum and add also repellency. Acute oral LD₅₀ for rats is 450 mg/kg (acute percutaneous LD₅₀ >5,000 mg/kg). Very low toxicity for birds and fish was measured. In rats imidacloprid is quickly absorbed from the gastrointestinal tract and eliminated to 96 % within 48 h mainly via the urine. 15 % was eliminated unchanged. The most important metabolic steps were hydroxylation at the imidazoline ring, hydrolysis to 6-chloronicotinic acid, loss of the nitro group with formation of the guanidine, and conjugation of 6-chloronicotinic acid with glycine. Nitenpyram is an insecticide with contact and stomach action similar to imidacloprid. It has been very recently introduced in selected markets as an oral formulation for acute treatment of fleas on pets. Upon oral administration, ectoparasiticide activity lasts not more than 3 days due to the quick elimination and excretion of the compound via urine. Nitenpyram is marketed only in combination with longer-acting compounds. Acute oral LD₅₀ for rats is 1,600 mg/kg (acute percutaneous LD₅₀ > 2,000 mg/kg).

Resistance

More than 10 years after the introduction of imidacloprid as a pet flea product, field resistance of ectoparasites against imidacloprid has not been reported. Laboratory trials with the multiresistant (organophosphates, carbamates, pyrethroids, benzoylphenyl ureas, cyclodienes) field strain “cottontail” from Florida revealed no cross resistance for imidacloprid to other flea insecticides. It can be speculated from data obtained with

insects relevant to crop protection (aphids, whiteflies) that mechanisms of detoxification of neonicotinoids in fleas will be based on similar mechanisms. For whitefly and aphids, the dominant route of detoxification relies predominantly on oxidative processes; however, some of the first step oxidation products retain insecticidal activity. To date, no target insensitivity was observed in insect ectoparasites collected from the field. Susceptibility to imidacloprid was not significantly different in housefly strains resistant against organophosphates or pyrethroids, respectively, compared to fully susceptible flies. Generally, the housefly is less susceptible to neonicotinoids. This could be due to fast detoxification by mixed-function oxidases as can be concluded from experiments enhancing the efficacy of neonicotinoids against houseflies through ► [syn-ergists](#) like piperonyl butoxide. Additionally, slow penetration through the cuticle of the housefly is also discussed. Besides the metabolic detoxification, a point mutation has been identified very recently in $\alpha 1$ and $\alpha 3$ subunits of nicotinic acetylcholine receptors from field strains of plant hoppers after further selection in the laboratory. After more than 15 years of use as crop insecticides in the field, this is the first target site mutation. It turned out recently that this Y151S point mutation causes reduced agonist potency to the whole range of known neonicotinoids. Dinotefuran as the weakest agonist turned out to be the compound that is least affected by the mutation. However, this point mutation has yet to be identified in field populations of ectoparasites.

Twelve-Membered Macrocyclic Lactones

Important Compounds: Spinosad and Spinetoram

Spinosad is the first product introducing a new class of 12-membered macrocyclic lactones, a mixture of spinosyn A and spinosyn D, isolated from extracts of *Saccharopolyspora spinosa*. Recently the product class was broadened by spinetoram, a mixture of spinosyn J and spinosyn L, slightly chemically modified. The mode of action is similar to that of neonicotinoids though a different subtype

of nicotinic acetylcholine receptors is agonistically targeted by these molecules. The compound is marketed as a wound dressing and insecticide against blowfly on sheep and against flies and lice on cattle. The compound is used as an oral monthly treatment in dogs against fleas. Efficacy against fleas is on the same level as with neonicotinoids. Recently the compound has also been combined with milbemycin oxime to cover also intestinal parasites with a single monthly treatment. Spinosad has gained FDA approval for head lice treatment in humans in 2011. For spinosad the acute oral toxicity LD₅₀ for male and female rats is 3,738 mg/kg and >5,000 mg/kg body weight, respectively. Acute dermal toxicity is >2,000 mg/kg in rabbits. Acute inhalation LC₅₀ in rat is >5.18 mg/l. Spinosad technical (90 %) is slightly irritant to eyes of rabbits but it is not a skin sensitizer in guinea pigs. At >2,000 mg/kg body weight, no acute neurotoxicity has been observed. The compound has a half-life of approximately one day in aqueous solution under sunlight. No bioaccumulation has been found in fish. In rat spinosad is rapidly absorbed and extensively metabolized. The compound is slightly respectively moderately toxic to birds, fish, and aquatic life and highly toxic to bees.

Spinetoram which recently has been introduced as a topical flea treatment for cats is not considered to be toxic to mammals. The LD₅₀ for acute oral toxicity in rats is >5,000 mg/kg. Upon inhalation, the LC₅₀ for rats is >5.5 mg/L. The acute percutaneous toxicity in rabbits has an LD₅₀ >5,000 mg/kg. Eye contact with spinetoram formulations may cause slight irritation. So far there were no indications of mutagenicity, teratogenicity, or oncogenicity (negative in Ames and chromosomal aberration tests, mutation and mouse bone marrow micronucleus assays). The acute and chronic toxicity of spinetoram to mammals, birds, fish, earthworms, and aquatic plants is low. Spinetoram is toxic to aquatic invertebrates from chronic exposure. However, because of its rapid degradation in aquatic systems, spinetoram is not expected to impact these species negatively. The compound is toxic to honeybees, but residues aged 3 h or longer are practically nontoxic, and the compound is rapidly degraded in soil (DT₅₀ 3–5 days) and water (DT₅₀ <1 day).

Resistance

No resistance of ectoparasites against spinosad or spinetoram has been described since the compounds are relatively new to the market. Some crop pests have been shown to develop spinosad resistance in the meantime, and detailed studies helped to elucidate the potential target for spinosyns on nicotinic acetylcholine receptors of insects. Other than neonicotinoids, the spinosyns seem to recognize nAChR that contain alpha-6-like subunits. Mis-spliced transcripts of nicotinic acetylcholine receptor alpha-6 subunits were found to be associated with field evolved spinosad resistance in the diamondback moth *Plutella xylostella* (L.). Another study identified a nicotinic acetylcholine receptor alpha-6 subunit transmembrane point mutation in spinosad-resistant western flower thrips *Frankliniella occidentalis*. Fruit fly alpha-6 nAChR gene knockdown resulted in >1,000-fold spinosad resistance confirming the findings from the field.

Ectoparasiticides: Antagonists and Modulators of Chloride Channels

Andreas Turberg

Bayer Healthcare AG, Bayer Animal Health GmbH, GDD-AH-PARA-APR, Monheim, Germany

Mode of Action

(See Fig. 1.)

Structures

(See Fig. 2.)

Organohalogenides

Important Compounds

Chlordane, bromocyclene, endosulfan, lindane, heptachlor, toxaphene

General Information

Lindane was isolated from the mixture of isomers in 1912. In 1943 lindane was identified as the insecticidal principle of hexachlorhexane. Insecticidal properties of chlordane, a cyclodiene, were at first identified in the 1940s. The action of lindane and cyclodienes to stimulate synaptic transmission was demonstrated 40 years ago. However, it was not until the early 1980s that the GABA-gated chloride channel complex was suggested to be their target site. In nerve and muscle preparations, lindane and cyclodiene insecticides antagonized GABA-stimulated ^{36}Cl uptake and competed with the TBPS (t-butylbicyclophosphorothioate) binding site at the GABA-gated chloride channel. Recent studies with cockroach neurones revealed that lindane and cyclodienes decrease the frequency of the GABA-gated chloride channel opening without changing the mean opening time. Dieldrin suppressed the GABA-induced current in a noncompetitive manner. Since picrotoxin

Ectoparasiticides: Antagonists and Modulators of Chloride Channels, Fig. 1 Model of drugs affecting neuromuscular transmission by inhibitory neurotransmitters

attenuates the inhibitory effect of dieldrin, it is speculated that cyclodienes bind to the picrotoxin/TBPS binding site. It follows that lindane and cyclodienes are antagonists at GABA-gated chloride channels directly responsible for excitatory symptoms in poisoning of mammals and insects.

Chlordane (cyclodiene compound) is a nonsystemic insecticide with contact, stomach, and respiratory action and long residual activity.

It controls household insects as well as pests of domestic animals and man. The compound has impurities of different stereoisomers and heptachlor. Acute oral LD₅₀ for rats is 133–649 mg/kg (acute percutaneous LD₅₀ 217 mg/kg). The compound accumulates in body fat and lipid-containing organs. It shows serious chronic and cumulative toxicity. The compound is toxic to fish and bees. In mammals, chlordane is metabolized mainly to hydroxylated products. Bromocyclene

Ectoparasiticides: Antagonists and Modulators of Chloride Channels, Fig. 2 Structures of antiparasitic drugs affecting GABA- or glutamate-gated chloride

channels (for structures of avermectins, see Nematocidal Drugs, Animals, Nematocidal Drugs, Man)

is a nonsystemic insecticide with contact and stomach action. It is used against ectoparasites in sheep and against fleas on pets. Endosulfan (cyclodiene compound) is a nonsystemic insecticide with contact and stomach action. In animal and public health applications, it is used for the control of tsetse flies. Acute oral LD₅₀ for rats is 70–240 mg/kg depending on isomer and formulation (acute percutaneous LD₅₀ > 4,000 mg/kg).

Endosulfan is toxic to fish *in vitro* but no toxicity has been observed under field conditions. The compound shows no significant toxicity to bees. In mammals, endosulfan is eliminated via the feces within 48 h. Residues accumulate in the kidney rather than in fat but are eliminated with a half-life of 7 days. The compound is rapidly metabolized to less toxic metabolites and to polar conjugates. Lindane (γ -HCH) is one

(>99 %) isomer of the technically synthesized mixture of hexachlorhexane isomers. It is an insecticide with contact, stomach, and respiratory action and controls a broad spectrum of insects in public health and animal ectoparasites, e.g., mites, sucking and biting lice, and ticks. Acute oral LD₅₀ for rats is 88–270 mg/kg depending on the carrier (acute percutaneous LD₅₀ 900–1,000 mg/kg). The compound shows toxicity to fish and to bees. In mammals, lindane is found in the milk, body fat, and kidney after oral administration but rapid elimination occurs. Metabolites formed are less chlorinated compounds which are excreted as glucuronic acid conjugates.

Resistance

Most of the organohalogenide compounds have been withdrawn from the market for toxicological and environmental reasons. From 1948 to 1954, chlorinated hydrocarbons like DDT (see entry [▶ Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels](#)"/Organohalogenides) and dieldrin were extensively used for fly-strike control. The 1954 field monitoring detected no resistant blowfly populations, whereas in 1958, the year of the withdrawal of aldrin/dieldrin insecticides for sheep treatment, 70 % of the fly strains tested were resistant to dieldrin. The fast development of resistance against dieldrin was speculated to be preselected by the previous use of lindane, increasing the frequency of the rdl gene (encoding for a dieldrin insensitive insect GABA receptor; see below). Resistance against this class of compounds is still present in the ectoparasite populations. For dieldrin resistance, e.g., in blowfly populations, 2–3 % of the individuals still show the resistant phenotype. Therefore, application of selection pressure with new insecticides cross-resistant with this phenotype will favor the resistant individuals leading again to resistant populations in a few generations. Resistance against lindane was reported for Australian strains of the cattle tick *Rhipicephalus (Boophilus) microplus*. Molecular biology techniques enabled the identification of the cyclodiene resistance-mediating gene (rdl) that was identified as a member of the ligand-gated chloride channel gene family sensitive to GABA.

Macrocyclic Lactones

Sixteen-membered macrocyclic lactones

Important Compounds

Doramectin, eprinomectin, ivermectin, latidectin, milbemycin oxime, moxidectin, selamectin

General Information

The class of 16-membered macrocyclic lactones comprises two families: the avermectins and the milbemycins. The avermectins have been discovered by Omura at the Kitasato Institute in Japan. The compounds are active against ecto- and endoparasites and thus defined as endectocides. The biochemical mode of action is multifunctional. Recent reports established that the major target of the avermectins is the glutamate-gated chloride channel. The compounds also exert modulatory agonistic activity at the GABA-gated chloride channel, thus causing paralysis. Detailed discussion of the mode of action of avermectins and target site identification has been described in [▶ Nematocidal Drugs, Animals](#), and [▶ Nematocidal Drugs, Man](#). The following compilation concentrates on the ectoparasitidal activities of the macrocyclic lactones.

Doramectin is a broad-spectrum insecticide and acaricide with contact and stomach action. The 25-cyclohexyl-ivermectin B₁ compound was the fourth avermectin derivative introduced into the animal health market. It is a fermentation product of a mutant *Streptomyces avermitilis* strain. The lipophilic cyclohexyl moiety seems to be responsible for the greater tissue half-life of doramectin. It is used as a systemic endectocide with ectoparasitidal activity against warble fly, screwworm, lice, mite, and ticks including multiresistant strains. Eprinomectin is an ivermectin derivative with an amino modification of the bisoleandrosyl moiety resulting in enhanced insecticidal efficacy and favorable pharmacokinetics with no withdrawal periods for meat and milk. The compound retains the insecticidal and acaricidal properties of ivermectin. Eprinomectin was introduced into the market as an endectocide in 1997. Ivermectin is a potent insecticide and acaricide with stomach and contact action. The product is a semisynthetic derivative of

ivermectin analogue of *Streptomyces avermitilis* and consists of 22,23-dihydroavermectin B_{1a} and 22,23-dihydroavermectin B_{1b} (4:1 mixture). The compound is used in different formulations (injectable, pour on, bolus) against ticks, sucking and biting lice, cattle grubs, mites, horn flies, and botflies. Withdrawal period for meat is 28 days. Ivermectin is not allowed for use with cattle producing milk for human consumption. Withdrawal period for dairy cows is 28 days prior to calving. Acute oral LD₅₀ for rats is 10–50 mg/kg. The compound is toxic to fish and other aquatic organisms and toxic to honeybees. Excreted with feces, ivermectin is toxic to coprophagous insects. Latidectin is a new semisynthetic milbemycin derivative recently developed for treatment of intestinal nematodes and heartworm in pets. Milbemycin oxime is an insecticide, acaricide, and nematicide with contact and stomach action. The compound is a mixture of milbemycin A3 and milbemycin A4 (3:7) produced by *Streptomyces hygroscopicus*. Subsequent derivatization of the hydroxyl group at position five to a ketoxime resulted in a less potent compound with a favorable toxicological profile. The compound is predominantly active against nematodes and shows only weak ectoparasitocidal activities at the concentrations used in animal treatment. In combination with an insecticide, the compound is used against endoparasites and fleas in pets (lufenuron). Moxidectin, the third macrocyclic lactone introduced into the market of endectocides, is produced by a combination of fermentation and chemical synthesis by 23-methoxime derivatization of nemadectin, a milbemycin produced by *Streptomyces cyanogriseus noncyanogenus*. The efficacy against endo- and ectoparasite is comparable to that of ivermectin. Withdrawal periods are 28–49 days for meat depending on the product. The compound is less toxic to coprophagous insects when compared to ivermectin. In combination with an insecticide, the compound is used against endoparasites and ectoparasites like fleas and mites in pets (imidacloprid). Selamectin is a semisynthetic doramectin analogue which has been introduced into the market of pet endectocides in 1999. The compound is active against fleas, some ticks, intestinal hookworms, ascarids, and immature heartworms. The favorable toxicology profile was

achieved through introduction of a 5-ketoxime group and cleavage of one sugar moiety. An overview of the efficacy spectrum of avermectins active against ectoparasites in cattle is shown in (Table 1).

Resistance

Broad resistance of parasitic arthropods against avermectins or milbemycins in field isolates has not yet been reported. No cross-resistance has been found to other compounds. Reports of a milbemycin derivative breaking avermectin resistance of nematodes are under discussion. It is speculated that moxidectin has higher efficacy against specific nematodes compared to ivermectin leading to the control of ivermectin-resistant strains of these nematodes. A laboratory selection of sheep blowfly larvae with ivermectin was recently published. A pooled field strain was subjected to ivermectin treatment at a concentration producing more than 70 % mortality. The larvae were selected over 60 generations, giving a twofold increase in the LC₅₀ after the first selection and finally resulting in an eightfold resistant strain. After relaxation of the selection pressure, the selected strain reverted toward susceptibility fairly rapidly. Within eight generations, the LC₅₀ values dropped from sevenfold to twofold compared to the parental strain.

Phenylpyrazoles

Important Compounds

Fipronil, pyriprole

General Information

Phenylpyrazole intoxication of blowfly causes hyperexcitability and elevates nerve discharge. Inhibitory effects of GABA on *D. melanogaster* motor neurone discharge are reverted in a manner similar to that of picrotoxin and cyclodienes. Phenylpyrazoles are antagonists of the GABA-gated chloride channel, and there is evidence that these compounds share a common binding site with cyclodienes, TBPS, and picrotoxin on the GABA receptor.

Fipronil is a broad-spectrum nonsystemic insecticide and acaricide with contact and

stomach action and good residual activity. It is used for the control of ectoparasites of pets and livestock as well as an insecticide in public health. Acute oral LD₅₀ for rats is 97 mg/kg (acute percutaneous LD₅₀ > 2,000 mg/kg). Fipronil is harmful to some species of birds and fish and highly toxic to bees (direct contact and ingestion). In mammals, fipronil is rapidly distributed and

metabolized upon adsorption. Fipronil and its sulfone are eliminated mainly via the feces. Urinary metabolites have been identified as conjugates of ring-opened pyrazole products. Pyriprole is a new broad-spectrum ectoparasiticide which has been developed very recently for use against ticks and fleas on dogs. The compound is less toxic than fipronil and is thought to be a prodrug of the active compound with the free amine group. Acute oral LD₅₀ for rats is >300 mg/kg. Pyriprole is a moderate eye irritant and shows no dermal irritation potential.

Resistance

Analysis of the rdl (resistant to dieldrin) gene isolated from cyclodiene-resistant mosquitoes and flies showed a specific point mutation (A302S) responsible for the altered insecticide susceptibility of the target. Cyclodiene-resistant fruit fly strains showed a more than 25-fold resistance against phenylpyrazoles. Phenylpyrazole topical treatment of cyclodiene-resistant and cyclodiene-susceptible *Blattella germanica* resulted in LD₅₀ values of 40 and 0.07 $\mu\text{g/insect}$, respectively, indicating a 570-fold cross-resistance. A cyclodiene-resistant housefly strain showing nearly 2,900-fold resistance to dieldrin had an LC₅₀ value of 36 ppm for fipronil, whereas LC₅₀ of a susceptible reference strain was 0.4 ppm revealing a 90-fold cross-resistance. Perhaps more interestingly, despite the fact that the A302S mutation greatly reduces the rate of GABA receptor desensitization, the fitness of resistant flies does not seem to be decreased.

Recently molecular biology analyses of rdl genes in several flea strains from different areas throughout the world revealed a high prevalence of the point mutation conferring resistance to dieldrin. However, the practical relevance of this observation of potential phenylpyrazole cross-resistance on a molecular level has yet to be proven in in vivo trials on animal.

Arylisoxazolines

Important Compounds

Afoxolaner, fluralaner

General Information

The novel class of arylisoxazolines was originally invented by crop protection companies. Two molecules have now been developed for use in pets to treat ticks and fleas and will enter the market of ectoparasiticides 2014. The principal molecular target of arylisoxazolines is the GABA_A receptor where the compounds act as noncompetitive antagonists. Other than phenylpyrazoles, the compounds have a different binding site on GABA_A receptor subunits and do not bind with high affinity to the EBOB (ethynylbicycloorthobenzoate) site on $\beta 3$ subunits of rat brain GABA_A receptors. Comparison of effects on recombinant HEK293 cell lines expressing cattle tick glutamate or GABA-gated chloride channels revealed antagonistic activity of arylisoxazolines against both targets by suppressing the membrane potential sensitive fluorescent dye signal elicited by agonistic stimulation.

The arylisoxazoline potency on glutamate-gated channels was about 50-fold lower compared to GABA-gated chloride channels. In this study, the phenylpyrazole fipronil was fivefold less effective on GABA-gated chloride channels but showed slightly higher affinity to tick glutamate-gated chloride channels compared to arylisoxazolines.

Afoxolaner is a broad-spectrum systemic insecticide and acaricide with contact and stomach action and good residual activity. It is used for the systemic control of ectoparasites of dogs by administering the compound as a soft chewable. Acute oral LD₅₀ for rats is not published yet. Target animal safety information from dogs suggests a potential for accumulation with increasing serum levels after repeated application. In this study, no severe side effects or deaths have been observed. The current profile of tick and flea control comprises *Dermacentor variabilis*, *D. reticulatus*, *Ixodes ricinus* and *Rhipicephalus sanguineus*, and *Ctenocephalides felis* control for 4 weeks. Fluralaner is a broad-spectrum systemic insecticide and acaricide with contact and stomach action and good residual activity. It is used for the systemic control of ticks and fleas on dogs by administering

the compound as a soft chewable with a duration of efficacy period of up to 12 weeks. The dose rate used is about tenfold higher as with the afoxolaner chew with 1 month activity. The tick control spectrum comprises *Rhipicephalus sanguineus* and *Amblyomma americanum* (8-week control), *Ixodes ricinus*, *Dermacentor reticulatus*, and *D. variabilis* (12-week control). Standard mammal toxicity information has not yet been published.

Resistance

No resistance is known against these new compounds which also did not show any cross-reactivity with binding sites of known ectoparasiticides acting on ligand-gated chloride channels.

Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels

Andreas Turberg
Bayer Healthcare AG, Bayer Animal Health
GmbH, GDD-AH-PARA-APR, Monheim,
Germany

Mode of Action

See Fig. 1.

Structures

See Fig. 2.

Organohalogenides

Important Compounds

DDT, Methoxychlor.

General Information

DDT is a broad-spectrum insecticide introduced onto the market in 1943. Nowadays, the compound has been replaced by less persistent insecticides in nearly all countries. DDT is a persistent nonsystemic insecticide with contact and stomach action. DDT acts on the voltage-gated sodium channel causing slow opening and closing characteristics of the ion channel. This results in an increased negative after potential, prolonged action potentials, repetitive firing after single stimulus, and spontaneous trains of action potentials. Temperature has a profound effect on the insecticidal activity of DDT. Its potency to induce repetitive discharges from cockroach sensory neurons increases with lowering of the temperature with a Q_{10} of 0.2. While in most countries the use of DDT is prohibited by law, in some countries DDT is still used in mosquito eradication programs. Acute oral LD_{50} for rats is 113–118 mg/kg (acute percutaneous LD_{50} 2,510 mg/kg). DDT is toxic to fish and

aquatic life. A side effect of DDT is the inhibition of a Ca-ATPase that is necessary for the calcification of eggshells. The compound accumulates in fatty tissues of mammals and is excreted in milk. The high potential for bioaccumulation and its long persistence has been discussed to be a major hazard to the environment. Methoxychlor is an insecticide closely related to DDT with contact and stomach action. It is used for the control of insect pests in animal houses, dairies, and household. Acute oral LD_{50} for rats is >6,000 mg/kg. The compound is toxic to aquatic life and fish. In mammals the compound is degraded by *O*-dealkylation to the corresponding phenol and diphenol and by dehydrochlorination to 4,4'-dihydroxybenzophenone.

Resistance

Resistance of ectoparasites against DDT and methoxychlor is mainly of metabolic origin. Primarily, elevated levels of dehydrochlorinase activity together with mixed-function oxidases are involved in detoxifying DDT. Reduced penetration of DDT through the cuticular layers is another resistance mechanism, e.g., in DDT-resistant flies. Furthermore, DDT susceptibility is reduced in target-site mutant *kdr* and super-*kdr* housefly strains. Housefly strains resistant to DDT show reduced susceptibility for methoxychlor. However, methoxychlor-resistant flies are fully susceptible to DDT indicating a different mechanism for methoxychlor detoxification. A possible pathway could be demethylation and subsequent conjugation.

Pyrethrins

Important Compounds

Pyrethrin I, Pyrethrin II, Cinerin I, Cinerin II, Jasmolin I, Jasmolin II.

General Information

Pyrethrum comprises a mixture of naturally occurring pyrethrin (pyrethrin I, pyrethrin II, jasmolin I, jasmolin II, cinerin I, cinerin II) CNA: (Z)-(S)-2-methyl-4-oxo-3-(penta-2,4-dienyl) cyclopent-2-enyl (+)-*trans*-chrysanthemate

Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels, Fig. 1 Model of drugs affecting neural transmission at voltage-sensitive sodium channels

(cinerin I); (Z)-(S)-2-methyl-4-oxo-3-(penta-2,4-dienyl)cyclopent-2-enyl (+)-*trans*-chrysanthemate (pyrethrin I); (Z)-(S)-3-(but-2-enyl)-2-methyl-4-oxocyclopent-2-enyl (+)-*trans*-chrysanthemate (cinerin I); (Z)-(S)-2-methyl-4-oxo-3-(penta-2-enyl)cyclopent-2-enyl (+)-*trans*-chrysanthemate (jasmolin I); (Z)-(S)-2-methyl-4-oxo-3-(penta-2,4-dienyl)cyclopent-2-enyl pyrethrate (pyrethrin II); (Z)-(S)-3-(but-2-enyl)-2-methyl-4-oxocyclopent-2-enyl pyrethrate (cinerin II); and (Z)-(S)-2-methyl-4-oxo-3-(penta-2-enyl)cyclopent-2-enyl pyrethrate (jasmolin II) isolated from *Tanacetum* (= *Chrysanthemum* = *Pyrethrum*) *cinerariaefolium*. Pyrethrum is an ancient insecticide which was identified in China and spread to Dalmatia, France, the USA, and Japan in the nineteenth century (dried

powdered flower heads were called Persian insect powder). Pyrethrum is a nonsystemic insecticide with some acaricidal activity. It causes immediate paralysis with death occurring later and shows quick knockdown and short-acting activities. The primary molecular target of pyrethrins is the neuronal presynaptic voltage-sensitive sodium channel. Pyrethrum is used in treatment of ectoparasites on companion and farm animals. The biological efficacy of pyrethrins and pyrethroids seems to be less pronounced in the larval stage of most insect species which might be due to the higher activity of the adult stages compared to larvae. Generally, it is combined with synergists like piperonyl butoxide to encounter quick detoxification and to enhance potency. In mammals pyrethrins are rapidly

Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels, Fig. 2 Structures of antiparasitic drugs affecting voltage-sensitive sodium channels

degraded in the stomach by hydrolysis of the ester bond to nontoxic metabolites. The LD₅₀ for acute oral toxicity in rats is 584–900 mg/kg (LD₅₀ acute percutaneous toxicity >1,500 mg/kg in rats). Synergists seem not to enhance the toxicity of pyrethrins to mammals. Pyrethrins are highly toxic to fish and toxic to bees but show a repelling effect.

Pyrethroids

General Information

Pyrethrins served as a lead structure for the synthesis of the pyrethroids. The chemical class of pyrethroids is divided into structurally related subclasses. The type I pyrethroids are ester bond pyrethroids without α -cyano-residue; the type II pyrethroids include all ester bond pyrethroids containing a cyano-group at the α -carbon atom. An example for the class of non-ester bond pyrethroids is also given. A variety of structures were introduced onto the market during the 1970s and 1980s.

The insecticidal symptoms of type I pyrethroids are characterized by hyperexcitation, ataxia, convulsions, and paralysis. Type II pyrethroids cause hypersensitivity, tremors, and paralysis. The primary target of pyrethrins and all pyrethroids is the voltage-sensitive sodium channel on the presynaptic side of insect neuronal synapses. The pyrethroids' slow kinetics of both opening and closing of individual sodium channels results in delayed and prolonged openings. Pyrethroids also cause a shift of the activation voltage in the direction of hyperpolarization. There then follows a membrane depolarization and an increase in depolarizing afterpotential. The latter reaches the threshold for excitation causing repetitive afterdischarges. The membrane potential of sensory neurons increases the discharge frequency and that of nerve terminals increases the release of neurotransmitter and the frequency of spontaneous miniature postsynaptic potentials. The corresponding symptoms of mammalian or arthropod intoxication are hyperexcitation, hypersensitivity, convulsions, and tremors. As described for DDT, pyrethroids also show a negative temperature coefficient for

their activity on voltage-sensitive sodium channels revealing a Q_{10} value of 0.18 for tetramethrin between 25 °C and 35 °C. Type II pyrethroids also show some modulatory activity at a secondary target site identified as GABA-gated chloride channel.

Type I Pyrethroids

Important type I pyrethroids are allethrin, Bioallethrin, permethrin, phenothrin, resmethrin, and tetramethrin. Allethrin [(1R)-isomers] is a nonsystemic insecticide with contact, stomach, and respiratory action. It gives rapid knockdown and paralysis before killing. It is used for insect control in animal houses and as an animal ectoparasiticide. LD₅₀ of acute oral toxicity for rats is 900–2,150 mg/kg. In mammals the compound is detoxified after oral administration in the liver by oxidation of one terminal methyl group of the chrysanthemic acid moiety to a carboxyl group via an alcohol group. The compound is eliminated via urine and feces within 2–3 days after treatment. Bioallethrin, *D-trans*-allethrin [≥ 93 % (1R)-, ≥ 90 % *trans*, ≤ 3 % *cis*-isomer], is a potent contact nonsystemic, non-residual insecticide producing rapid knockdown. It is used mainly in household and public health and in some countries is marketed for ectoparasite treatment of companion animals. Mammalian toxicity is slightly higher than with allethrin. Detoxification and elimination occurs as described for allethrin. *Cis/trans* isomerization has not been observed in soil. Permethrin is a nonsystemic insecticide with contact and stomach action and slight repellent effect. It is used for repellence and control of biting flies and is also active against biting and sucking lice on cattle. Recently the repellence and acaricidal efficacy of permethrin have been used in a combination product against ticks and fleas, flies, and mosquitoes on dogs (imidacloprid). Acute oral LD₅₀ for rats is 4,000 and 6,000 mg/kg for a *cis/trans* isomer mixture of 40:60 and 20:80, respectively (acute percutaneous LD₅₀ > 4,000 mg/kg). Permethrin is toxic to fish and bees. In mammals hydrolysis of the ester bond occurs and the compound is eliminated as the glycoside conjugate. Phenothrin [(1R)-isomers] is a nonsystemic insecticide with contact and

stomach action that gives rapid knockdown. It is used in public health against a variety of injurious and nuisance insects and as a combination product with allethrin or tetramethrin for control of fleas and ticks on dogs and cats. Acute oral LD₅₀ for rats is >10,000 mg/kg (acute percutaneous LD₅₀ > 10,000 mg/kg). The compound is toxic to fish and bees. Resmethrin is a nonsystemic insecticide with contact action, acting in a similar manner to the natural pyrethrins but is not synergized by pyrethrum synergists. It is often used in combination with more persistent insecticides. Acute oral LD₅₀ for rats is >2,500 mg/kg (acute percutaneous LD₅₀ > 3,000 mg/kg). The compound is toxic to fish and to bees. Metabolism in hens was principally by ester hydrolysis and oxidation, followed by conjugation. Tetramethrin is a nonsystemic insecticide with contact action that gives rapid knockdown. It is used as flea insecticide for pets. Tetramethrin is often combined with synergists or other pyrethroid insecticides. Acute oral LD₅₀ for rats is >4,640 mg/kg (acute percutaneous LD₅₀ > 5,000 mg/kg). The compound is toxic to fish and to bees. Tetramethrin seems to be metabolized in a similar way to the natural pyrethrins. In mammals, following oral administration, about 95 % of the metabolized tetramethrin is eliminated in the urine and feces within 5 days. The principal metabolite is 3-hydroxycyclohexane-1,2-dicarboximide.

Type II Pyrethroids

Important type II pyrethroids are alpha-cypermethrin, cyfluthrin, cyhalothrin, cypermethrin, deltamethrin, fenvalerate, flucythrinate, flumethrin, and tau-fluvalinate. Alpha-cypermethrin (formerly also known as alphasmethrin) is a nonsystemic α -cyano-pyrethroid with contact and stomach action. It is used mainly to control body lice and blowfly strike on sheep with no withdrawal period required. Acute oral LD₅₀ for rats is 474 mg/kg (acute percutaneous LD₅₀ > 2,000 mg/kg; tech. grade). The compound is toxic to fish and bees under experimental conditions, but no toxic effects could be observed under field conditions. Cyhalothrin is a nonsystemic insecticide and acaricide with contact and stomach action and repellent properties. It is mainly used for control of animal

ectoparasites on sheep and cattle. Acute oral LD₅₀ for rats is 114–166 mg/kg (acute percutaneous LD₅₀ 200–2,500 mg/kg). The compound is toxic to fish and other aquatic organisms. In mammals the orally administered compound is hydrolyzed at its ester bond and polar conjugates are formed from both moieties. Cyhalothrin is rapidly eliminated via urine and feces. Cyfluthrin is a nonsystemic insecticide with contact and stomach action with rapid knockdown efficacy and long residual activity. The compound is used in public health, against stored product pests and against flies in animal health. Acute oral LD₅₀ for rats is 590 mg/kg (acute percutaneous LD₅₀ > 5,000 mg/kg). Toxicity to bees and fish has been observed. Cyfluthrin was largely and quickly eliminated in mammals. Ninety-eight percent of the administered amount was eliminated within 48 h via urine and the feces. Cypermethrin is a nonsystemic insecticide and acaricide with contact and stomach action. It also deters ovipositioning blowflies on treated sheep. It has a broad activity against ectoparasites on farm animals. Withdrawal periods are 7 days for meat and at least 6 h for milk. Acute oral LD₅₀ for rats is 200–800 mg/kg (acute percutaneous LD₅₀ > 1,600 mg/kg). The compound is toxic to fish and bees. Deltamethrin is a nonsystemic fast-acting insecticide and acaricide with contact and stomach action. It is used against a variety of ectoparasitic species on livestock. Acute oral LD₅₀ for rats is 128–139 mg/kg (acute percutaneous LD₅₀ > 5,000 mg/kg in aqueous solution). The compound is toxic to fish and bees under experimental conditions, but exhibits a repellent effect. Fenvalerate is a nonsystemic insecticide and acaricide with contact and stomach action. It controls a broad spectrum of parasitic arthropods and exhibits repellent activity. Acute oral LD₅₀ for rats is 451 mg/kg (acute percutaneous LD₅₀ > 2,500 mg/kg). The compound is toxic to fish and bees. In mammals fenvalerate is rapidly metabolized. Up to 96 % of the compound administered orally is excreted in the feces within 6–14 days. Flucythrinate is a nonsystemic insecticide with contact and stomach action. It is registered for the control of flies, fleas, and other insects. Acute oral LD₅₀ for rats is 67–81 mg/kg. The compound is moderately toxic to fish and toxic to bees but shows a repellent effect. In mammals flucythrinate is

eliminated within 24 h (60–70 %) to 8 days (>95 %) in the feces and urine. Major metabolic pathways are hydrolysis followed by hydroxylation of the hydrolysis products. Flumethrin is a nonsystemic insecticide and acaricide with contact and stomach action. It is used for the control of ticks, biting and sucking lice, and mites and for diagnosis and control of varroaosis in beehives. At sublethal doses a sterilizing effect of the pour-on formulation has been demonstrated for *Hyalomma* ticks. Specific formulations have been granted nil withdrawal periods for meat and milk. Acute oral LD₅₀ for rats is mg/kg (acute percutaneous LD₅₀ mg/kg). The compound is moderately toxic to fish and shows low toxicity to bees which enables for selective treatment against *Varroa* mites. Tau-fluvalinate is a nonsystemic broad-range insecticide and acaricide. In animal health applications it is marketed as for the control of the *Varroa* mites in beehives. Acute oral LD₅₀ for rats is >3,000 mg/kg (acute percutaneous LD₅₀ > 20,000 mg/kg). Tau-fluvalinate is toxic to fish and other aquatic organisms.

Non-ester Pyrethroids

Etofenprox is a non-ester pyrethroid insecticide with contact and stomach action. The compound is mainly used in crop protection but is also used to control public health pests and on livestock against insects. Recently the compound has also been registered for use against ectoparasites on cats. Acute oral LD₅₀ for rats is >42,880 mg/kg (acute percutaneous LD₅₀ > 2,140 mg/kg). The compound is slightly toxic to fish.

Resistance

Pyrethroid-resistant strains of the cattle tick *Boophilus microplus* have been isolated in countries in Central and Southern America, Southern Africa, and Australia. Resistance of Australian strains of *B. microplus* against pyrethroids has been reviewed by J. Nolan. Monitoring of horn fly control measures with pyrethroid dips, sprays, or pour-ons revealed significantly reduced susceptibility. The period of spray efficacy fell from 30 to 20 and even to 5 days in some areas of Argentina. Dips regularly able to control horn flies for 15 days protected animals ranging from 0 to 6 days. Pour-ons of deltamethrin, cypermethrin,

cyhalothrin, or cyfluthrin experienced a decline in efficacy from 45 to 60 days down to less than 4 weeks during the study. Since 1981 pyrethroids have been used as ectoparasiticides against sheep lice as pour-on or wet-dip formulations. By mid-1985 reports of failures of the pour-on pyrethroids were becoming more frequent. About 7 years later a lice strain was isolated in New South Wales (Australia) that was found to be 642× resistant to cypermethrin and able to survive pour-on and full-immersion dips. Addition of piperonyl butoxide to the formulation resulted in 81 % reduction of lice number again. Knockdown-resistant (kdr) and super-kdr (skdr) phenotypes have first been described in several housefly strains of different origins. Point mutations responsible for pyrethroid and DDT resistance have been identified in the coding region of the para sodium channel gene (the insect analogue of the vertebrate voltage-sensitive sodium channel) from kdr and skdr strains of the housefly as well as kdr strains of the German cockroach. Meanwhile many skdr and kdr mutations have been found in a variety of arthropods including ectoparasites and hygiene pests. In the case of cattle tick, human head louse (*Pediculus humanus capitis*), horn fly, and buffalo fly (*Haematobia irritans*), such mutations were identified in a pyrethroid-resistant field isolate and showed reduction of sodium channel sensitivity to pyrethroids in *Xenopus* oocyte functional expression electrophysiological studies. The location of such mutations and new high-resolution crystal structures of bacterial sodium channels allowed for modeling approaches to explain pyrethroid interaction with arthropod voltage-gated sodium channels.

Sodium Channel Inhibitor (SCI) Insecticides

Important Compounds

Metaflumizone, Indoxacarb.

General Information

The discovery of the structurally diverse class of sodium channel inhibitor (SCI) insecticides dates

back nearly four decades. Two derivatives also relevant in crop protection have been developed as commercial ectoparasiticides against fleas on cats and dogs – metaflumizone and more recently indoxacarb. SCI insecticides selectively bind to slow-inactivated (nonconducting) sodium channel states, thus inhibiting sodium channel function. Biochemical and electrophysiological studies suggest a binding site close to the local anesthetic receptor. This mode of action and different binding sites make SCI insecticide unique among other known insecticidal agents acting on sodium channels (e.g., organohalogenides, pyrethroids). However, compared to pyrethroid insecticides, onset of action is slow and SCI compounds lack the contact-repelling properties known for many pyrethroid derivatives. Poisoning symptoms with SCI insecticides are associated with an initial disruption of motor coordination and locomotion and subsequent pseudoparalysis. In mammals indoxacarb showed no effect on $\text{Na}_v1.4$ -subtype voltage-gated sodium channels but were most sensitive to its *N*-decarbomethoxylated active metabolite. Subtypes $\text{Na}_v1.2$, $\text{Na}_v1.8$, and $\text{Na}_v1.5$ were less sensitive. Since metabolic activation of indoxacarb is much more efficient in insects than in mammals, the compound has a good safety profile.

Metaflumizone, a semicarbazone derivative, has been launched in 2007 for use against fleas on cats as a single active application and against ticks and fleas on dogs in combination with an acaricide (amitraz). The acute oral and dermal LD_{50} in rat is $>5,000$ mg/kg bodyweight. Inhalation toxicity LC_{50} in rats is >5.2 mg/L. Metaflumizone is nonirritant to the eyes or skin of rabbits. The compound is not a sensitizer in guinea pigs. Treatment of dogs with a metaflumizone combination product with amitraz was recently linked to an increased incidence of pemphigus foliaceus cases (the most common spontaneously occurring autoimmune skin disease in dogs) which ultimately led to discontinuation of marketing of these products in 2011. Indoxacarb is an oxadiazine derivative that was first launched in crop protection in 2000. The compound has recently been introduced for use against fleas on cats and dogs and in combination

with permethrin for a broader ectoparasite spectrum on dogs. Indoxacarb is a prodrug that requires *N*-decarbomethoxylation to become an active metabolite. The acute oral (LD_{50}) in female rats is 179 mg/kg, and in male rats it is 843 mg/kg body weight. The acute dermal toxicity in rats had an LD_{50} of $>5,000$ mg/kg. Inhalation toxicity LC_{50} in rats is >4.2 mg/L. In contact in rabbits, indoxacarb (*S*-isomer) is nonirritant to the eyes and skin. In guinea pigs the compound showed a potential for skin sensitization. A standard array of in vitro and in vivo tests was conducted to determine the genotoxic, reproductive, and teratogenic potential of indoxacarb. The results of a series of studies indicated that there are no genotoxic, mutagenic, reproductive, developmental, or teratogenic hazards associated with the use of indoxacarb.

Resistance

Resistance of ectoparasites to metaflumizone or indoxacarb has not been reported since these molecules have been introduced only recently to animal health markets. For indoxacarb esterolytic activities conferred high levels of resistance in leaf rollers. In houseflies mixed-function oxidases (MFO) were found to be responsible for a 118-fold laboratory selected indoxacarb resistance in houseflies. A recent study on indoxacarb-resistant diamond-back moth revealed no apparent cross-resistance to metaflumizone. A cross-resistance against *kdr* or *skdr* pyrethroid resistance is not to be expected. Several authors found negative cross-resistance between pyrethroid resistance and elevated indoxacarb efficacy in lepidopteran species.

Ectoparasiticides: Inhibitors of Arthropod Development

Andreas Turberg

Bayer Healthcare AG, Bayer Animal Health GmbH, GDD-AH-PARA-APR, Monheim, Germany

Mode of Action

See Fig. 1.

Structures

See Fig. 2.

Chitin Synthesis Inhibitors

Important Compounds

Diflubenzuron, fluazuron, lufenuron, and triflumuron.

General Information

The chemical class of benzoylphenylurea (BPU) compounds is widely used as an insecticide also in animal health applications. The BPU compounds are inhibitors of chitin synthesis, thus interfering with the formation of the insect cuticle. There is no inhibition of other poly-sugar synthesis pathways (e.g., hyaluronic acid synthesis) by BPU compounds indicating high specificity. The biochemical target within the chitin biosynthesis pathway has not yet been clearly identified. Recent findings showed interference of BPUs with GTP-mediated Ca-transport in intracellular vesicles in chitin depositing integument cells from American cockroaches. Chitin synthase itself is not inhibited by BPU compounds. The inhibition of chitin synthesis by BPU compounds depends on intact cells. Diflubenzuron is a nonsystemic insect growth regulator with contact and stomach action. It shows activity against molting larvae or hatching eggs. The acute oral LD₅₀ for rats is >4,640 mg/kg (acute percutaneous LD₅₀ > 10,000 mg/kg). The compound shows very low toxicity for fish and is not toxic to bees and predatory insects. In mammals diflubenzuron is partly eliminated as the parent compound with the feces following oral administration. The other part is excreted mainly as hydroxylated metabolites. Fluazuron is a nonsystemic ixodid growth regulator with contact and stomach action. The compound was recently launched for strategic tick control in Australia. It shows activity against all developmental stages of the cattle tick *Rhipicephalus (Boophilus) microplus* including all resistant strains. The acute oral LD₅₀ for rats is >5,000 mg/kg (acute percutaneous LD₅₀ > 2,000 mg/kg). Acatak has a withdrawal period of 42 days and treatment of dairy cows and suckling cattle is not allowed. The compound is harmful for fish but not toxic to bees. In mammals the compound is virtually not metabolized following oral administration. Lufenuron is an insect growth

Ectoparasiticides: Inhibitors of Arthropod Development, Fig. 1 Model of drug interaction with arthropod development

Ectoparasiticides: Inhibitors of Arthropod Development, Fig. 2 Structures of ectoparasiticidal drugs interfering with arthropod development

regulator that mostly acts by ingestion. The compound has been introduced in the pet market as a systemic flea growth regulator. Adult fleas feeding from blood of systemically treated animals lay non-fertile eggs. Larvae feeding from feces produced by treated adult fleas will be unable to molt and also cease feeding. The compound is also used in combination with macrocyclic lactones against endoparasites and fleas in pets (milbemycin oxime). The acute oral LD_{50} for rats is $>2,000$ mg/kg (acute percutaneous LD_{50}

$>2,000$ mg/kg). The compound shows very low toxicity for fish and is only slightly toxic to adult bees. In mammals lufenuron is mainly eliminated as the parent compound with the feces following oral administration. Triflumuron is a nonsystemic insect growth regulator with stomach action. It shows activity against molting larvae and causes infertility of eggs. The compound is used against blowfly, fly larvae in animal houses, cockroaches, and flea larvae. The acute oral LD_{50} for rats is $>5,000$ mg/kg (acute percutaneous

$LD_{50} > 5,000$ mg/kg). Triflumuron shows very low toxicity for fish and is not toxic to predatory insects. In mammals the compound is metabolized by hydrolytic cleavage-forming conjugated or partly hydroxylated metabolites containing the 2-chlorophenyl ring and correspondingly the 4-trifluoromethyl-methoxyphenyl ring.

Resistance

In animal health, resistance of ectoparasites against BPU is still rare. This might change with the growing market share of BPU as a sheep ectoparasiticide. In diflubenzuron-resistant strains of the housefly *Musca domestica*, oxidation seems to be the predominant route of detoxification. Other mechanisms of detoxification of BPUs are hydrolases as could be demonstrated by the synergizing effect of esterase inhibitors. Metabolic resistance against BPU has been demonstrated for a multiresistant housefly population. Glutathione-S-transferase and mixed function oxidase enzyme activities were determined and showed elevated levels. A multiresistant flea strain collected from Florida showed resistance to some BPU compounds in laboratory in vivo trials.

Juvenile Hormone Mimics

Important Compounds

Methoprene, hydroprene, fenoxycarb, and pyriproxyfen.

General Information

The class of insecticides comprises different chemical classes causing similar phenotypic damage to treated insects. They are mimics of the endogenous juvenile hormone of insects, preventing metamorphosis to viable adults when applied to larval stages. Juvenile hormone mimics also exert oviducal effects when applied to adults. Up to now, two primary targets of juvenoids have been identified. The compounds fulfill a dual function by inhibiting the juvenile hormone esterase from degrading endogenous juvenile hormone as well as by their weak agonistic effect on juvenile

hormone receptors. This adds to the endogenous juvenile hormone effects, thus compensating for the naturally occurring degradation of the juvenile hormone-producing corpora allata glands. In adult insects juvenile hormones are involved in the regulation of vitellogenesis of the eggs. Altering homeostasis in this developmental stage could cause infertile eggs. The complete cascade of effects remains to be established. Several candidates for the endogenous juvenile hormone receptor – in all probability a member of the ligand-activated nuclear transcription factor family – are currently under discussion in *Drosophila*, e.g., the gene products of ultraspiracle and methoprene tolerant. Juvenile hormones and juvenile hormone mimics act as suppressers and stimulators of gene expression depending on the developmental stage and type of regulated protein. Several genes under the control of juvenoids have been identified. This explains the variety of effects observed with juvenoid-treated insects.

Fenoxycarb is an insect growth regulator with contact and stomach action. The compound exhibits a strong juvenile hormone activity, inhibiting metamorphosis to the adult stage and interfering with the molting of early instar larvae. The acute oral LD_{50} for rats is $>10,000$ mg/kg (acute percutaneous $LD_{50} > 2,000$ mg/kg). The compound shows low toxicity for fish and is nontoxic to adult bees. In mammals, the major metabolic path for fenoxycarb is ring hydroxylation to form ethyl-[2-[p-(p-hydroxyphenoxy)phenoxy]ethyl]-carbamate. Hydroprene is an insect growth regulator closely related to methoprene, predominantly used against hygiene pests. Methoprene is an insect growth regulator (juvenile hormone mimic) preventing metamorphosis to viable adults when applied to larval stages. The compound is also used for the control of public health pests as well as in combination products against fleas on pets (fipronil). The acute oral LD_{50} for rats is $>34,600$ mg/kg. The compound shows very low toxicity for fish and is nontoxic to adult bees. In mammals, methoprene is metabolized to simple acetates and also cholesterol has been identified as a secondary metabolite. The metabolites

were present in milk and blood but have not been detected in tissues. Upon oral administration, methoprene is not metabolized and excreted via the feces and the urine. Pyriproxyfen is an insect growth regulator acting as a suppresser of embryogenesis and adult formation (juvenile hormone mimic). The compound has been introduced in the pet market as a potent flea growth regulator and is used for the control of public health insect pests. The compound is also used for the control of flea development in combination with adulticides against fleas on pets (imidacloprid). The acute oral LD₅₀ for rats is >5,000 mg/kg (acute percutaneous LD₅₀ > 2,000 mg/kg).

Resistance Against Juvenile Hormone Mimics

No resistance has occurred against juvenile-hormone-related ectoparasite treatments. In *Drosophila* the methoprene-tolerant (Met) mutation results in a high (100-fold) level of resistance to the synthetic juvenile hormone analogue methoprene. The expressed Met-gene product has a high binding affinity to juvenile hormone in the nM range. Though JH regulation is disrupted and associated with fitness cost in Met-mutant flies, the Met alleles have been shown to persist in wild-type populations. Methoprene resistance that could not be reversed by different synergists has also been found in mosquito strains from different locations in the USA.

Aminotriazines/Aminopyrimidines

Important Compounds

Cyromazine and dicyclanil.

General Information

Currently, two structurally closely related drugs are marketed as insect growth regulators against larvae causing myiasis in animals and developing fly larvae in manure. The first of them, cyromazine, entered the market in 1979. The biochemical mode of action remains unclear. Cyromazine has been tested in dihydrofolate reductase and

tyrosinase assays but showed no inhibition of these enzymes, while another study demonstrated an inhibition of dihydrofolate reductase. The compound is definitely not involved in inhibition of chitin synthase. There are strong hints on the involvement of cyromazine in sclerotization of the cuticle. Cyromazine has its highest efficacy against first-instar larvae and leads to changes in the elasticity of the cuticle which might cause physical instability and lesions in the cuticle, finally preventing further development. Cyromazine-treated *Lucilia cuprina* larvae do not show signs of cuticle apolysis. There was evidence of an abnormal continuous deposition of cuticle material by the epidermal cells. This also holds true for cuticle deposition in the foregut. The sum of observations is indicative of a fundamental interference with insect molting at the hormonal level. However, recent results from positional cloning of a cyromazine resistance gene (achieved by chemical mutagenesis) and RNAi gene product disruption in *Drosophila melanogaster* support the hypothesis that cyromazine interfere with nucleic acid metabolism.

Cyromazine is an insect growth regulator with contact action interfering with molt and pupation. The topically applied compound has a pronounced residual effect and protects sheep against blowfly strike for 8 weeks. There is a withdrawal period of 7 days for meat. Acute oral LD₅₀ for rats is 3,387 mg/kg (acute percutaneous LD₅₀ > 3,100 mg/kg). Cyromazine is nontoxic to fish and adult honeybees. The compound is efficiently excreted in mammals, mainly as the parent compound. Dicyclanil is an insect growth regulator recently introduced into the market. The compound prevents the development of larvae into pupae or adults when incorporated into the insect-breeding substrate. Dicyclanil shows a high specificity against developing flies and fleas. Its biological efficacy is higher compared to that of cyromazine. Acute oral LD₅₀ for rats is 520 mg/kg, and LC₅₀ for inhalation toxicity in rats is 3.2 mg/L (acute percutaneous LD₅₀ in rats is >2,000 mg/kg). The compound is not a skin or eye irritant in rabbit.

Resistance Against Cyromazine

Although 20 years of cyromazine treatment has passed, no proven resistance has been reported from the Australian blowfly. From all field strains assayed, only three strains had a few survivors at the discriminating dose, but these flies were unable to reproduce successfully. Cyromazine was able to control even a high-level multiresistant housefly strain with a slightly higher LC_{50} (tolerance factor 1.7). There seems to be no cross-resistance to other insecticides. The cyromazine-resistant *Drosophila* obtained by chemical mutagenesis also is cross-resistant to dicyclanil. While laboratory-selected *Musca domestica* strains showed cyromazine resistance levels of more than 100-fold, current field populations of the housefly found in Denmark, Brazil, and the USA show only low resistance levels and can be called less susceptible at best.

Structures

See Fig. 1.

Modulators/Agonists of Aminergic Transmission

Important Compounds

Amitraz and cymiazole.

General Information

Formamidines are agonists of the octopamine receptors in the arthropod nervous system, causing an increase in nervous activity, reduction of feeding, and disruption of reproductive behavior. Octopamine can act as a neurotransmitter, neuromodulator, or even as a circulating neurohormone in insects. Octopamine is involved in energy mobilization and stress responses. It has a function as a modulator of muscle contraction and controls the release of adipokinetic hormone. Formamidines have been shown to exert ovicidal effects in insects and acari. Additionally, formamidines of the chlordimeform type have been shown to efficiently inhibit monoamine oxidase from rat liver. Chlordimeform was withdrawn from the market in the late 1980s. General side effects of formamidines in mammals are possible alterations in the animal's ability to maintain homeostasis for at least 24 h after treatment. A symptom often observed with formamidine-treated mammals is a reversible sedative effect.

Amitraz is a nonsystemic formamidine acaricide and insecticide with contact and respiratory action. It has been shown that amitraz is rapidly metabolized in arthropods and that one metabolite (BTS-27271) shows a biological activity superior to that of amitraz itself. Therefore, it is thought that amitraz acts as a pro-insecticide and pro-acaricide. The tickicidal effect comes with an expelling action causing ticks to withdraw mouthparts rapidly and fall off the host animal. The compound is used as an animal ectoparasiticide for the control of ticks, mites, and lice on cattle, dogs, goats, pigs, and sheep. Recently, the compound has also been developed for use in dogs against fleas and ticks in combination with a sodium channel modulator (metaflumizone). The acute oral LD₅₀ for rats is 650 mg/kg (acute percutaneous LD₅₀ > 1,600 mg/kg). The compound is toxic to fish and other aquatic organisms, but rapid hydrolysis makes it unlikely that toxicity will be observed in natural aquatic systems. Amitraz shows low toxicity to bees and predatory insects. Withdrawal period for the compound in meat is 24 h (7 days for sheep). In mammals rapid breakdown occurs, and 4-amino-3-methylbenzoic acid and to a lesser extent *N*-(2,4-dimethylphenyl)-

Ectoparasiticides: Modulators/Agonists of Aminergic Transmission, Fig. 1 Structures of formamidines and iminophenylthiazolidines

N'-methylformamide are excreted as conjugates. Cymiazole (CGA 50439) is a nonsystemic iminophenylthiazolidine ectoparasiticide with contact and respiratory action. It shows a good killing effect as well as inhibition of viable egg production and has a pronounced detaching effect on ticks. Cymiazole is also used as a systemic compound against *Varroa* mites feeding on bees carrying the compound in their body fluid. The compound has a 3-day withdrawal period for meat and can be used in milk-producing cattle without restrictions. Cymiazole has an acute oral LD₅₀ for rats of 725 mg/kg (acute percutaneous LD₅₀ > 3,100 mg/kg). The compound shows only weak toxicity to fish and shows no significant toxicity to bees.

Resistance

Resistance against amitraz has been observed in several strains of the southern cattle tick in Australia and Latin America. No resistance against amidine acaricides was found in multi-host ticks so far, with the exception of one case of moderate resistance against amitraz in multiresistant *Rhipicephalus sanguineus* strains recently isolated from large quarantine kennels. Amitraz resistance was also confirmed in *Varroa* mites on bees.

Ectopic Infections

Infections of other than the usual organs, e.g., ► *Paragonimus* may occur not only in the lung but also in the brain, omentum, skin, and liver of their hosts.

Ectoplasm

The peripheral, electron-lucent part of the ► *cytoplasm* of many protozoans (► *Entamoeba histolytica*).

Edema

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the abnormal accumulation of fluid (lymph, blood) in tissues, lungs, or serous cavities in a body due to unbalanced fluid homeostasis. These edemas often occur as clinical signs of an infection with different parasites (e.g., Filariae, ► *Sarcocystis*, Schistosomes, cp bacteria, ► *Chagom*, Trypanosomiasis).

Edhazardia Species

Microsporidian species of insects proceeding meiosis and change of ploidy.

EEEV

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Eastern equine encephalitis virus. This virus is reproduced and transmitted to horses and humans by mosquitoes of the genus *Culiseta* in Eastern regions of North America and in whole South America. However, during bites of other

mosquitoes (*Aedes*, *Ochlerotatus*, *Coquillettidia*, etc.) the viruses may be transmitted mechanically. This virus belongs to the Sindbis-horse encephalitis group.

Eflornithine

Diffuormethylornithine (DFMO), agent against trypanosomiasis. Trypanocidal Drugs.

EGF

Epidermal growth factor.

Egg-Reappearance Period (ERP)

Time from oral infection with helminthic eggs until excretion of new ones by fertilised females.

► [Prepatency](#).

Ehrlich, Paul (1854–1915)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Paul Ehrlich was a German physician and a gifted researcher in the fields of microbiology, cell physiology, and immunology and was later called the father of chemotherapy. After studies and expeditions to Egypt and other countries and due to the personal experience to be infected with tuberculosis, he joined in 1891 the research group of Robert ► [Koch](#) at the Berlin Institute of Infectious Diseases, where he met famous coworkers (e.g., ► [Kitasato](#)) and cooperated with Emil von ► [Behring](#). In 1896, a special institute was created there for Ehrlich's research field (Institute for Serum Research and Serum Testing). His main discoveries were:

P Ehrlich

Ehrlich, Paul (1854–1915), Fig. 1 Photo of the late Paul Ehrlich in his institute (with gratitude of the Paul Ehrlich Institute)

1. Development of a dye (Gram staining), which made it possible to diagnose the different blood cells (this stain is still used today).
2. He worked successfully on the phenomena of acquired immunity and autoimmunity. His work was considered so important that he was awarded in 1908 with the Nobel Prize in Physiology or Medicine with respect to his results in immunity research.
3. Together with Emil von ► [Behring](#), who stayed also (until 1893) at the Berlin Institute of Infectious Diseases, and also with ► [Kitasato](#), he worked on the lifesaving diphtheria serum, which was later marketed by Hoechst AG in Frankfurt, but which became mainly connected with the name of Emil von Behring and thus was for long a matter of dispute between both heroes of research.
4. Ehrlich's work became the most famous when he (now already in Frankfurt) and his

Japanese coworker Sahachiro ► [Hata](#) discovered in the year 1909 that the compound 606 (► [arsphenamine](#)) was able to kill *Treponema pallidum*, the agent of syphilis (lues venerea, Morbus Schaudinn) which was named at this time as *Spirochaeta pallida* and one of the most common infectious diseases. This product was brought to the market (by Hoechst AG) under the name Salvarsan and became the first pure chemical medicament and was described as one of Ehrlich's "magic bullets" – chemical compounds that kill exclusively the targeted agent of disease and which opened the century of the chemotherapy of our days leading to the fact that today the Paul Ehrlich Institute at Frankfurt is the official German institution to regulate new pharmaceuticals (Fig. 1).

Ehrlichia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Honoring Paul Ehrlich (► [Ehrlich, Paul \(1854–1915\)](#)), a German Nobel Prize winner and coworker of Robert Koch (► [Koch, Robert \(1843–1910\)](#)).

General Information

Ehrlichia is a genus of bacteria being transmitted by ticks. *E. phagocytophila* (transmitted by *Ixodes* ticks) introduces the granulomatous ehrlichiosis in humans, horses, mice, and ruminants (Fig. 1); *E. canis* is the agent of the monocytic ehrlichiosis in dogs (transmitted by *Rhipicephalus sanguineus*), while *E. chaffeensis* introduces this disease in humans being transmitted by *Amblyomma* ticks in USA. *E. phagocytophilum* is synonym to *Anaplasma phagocytophilum*.

Ehrlichiosis

Anaemian disease in sheep, cattle, cats, and dogs due to the rickettsian agents (e.g., *Ehrlichia canis*, *Haemobartonella felis*, and *Anaplasma* spp.) transmitted by ► [ticks](#) (► [Tick Bites: Effects in Animals](#)). These rickettsial stages are spherical (genera *Anaplasma*, *Haemobartonella*) and are found on the surface of erythrocytes (*Haemobartonella*) or appear ovoid (genus

Ehrlichia) and are situated inside monocytes. In particular the intraerythrocytic stages of *Anaplasma marginale* of cattle may become misdiagnosed as ► [piroplasms](#).

Therapy

Haemobartonella: Tetracyclines; *Anaplasma*, *Ehrlichia*: Imidocarb (Imizol*). In humans *Ehrlichia sennetsu* (Japan, South-East Africa) and *E. chaffeensis* (USA) may occur and are apparently also tick transmitted. They cause fever, ► [vomiting](#), nausea, which may, however, be self-limiting.

This term describes oxygen-containing derivatives of several times saturated C₂₀ fatty acid, which work as tissue hormones or as mediators and can be reactivated within minutes.

EIA

Enzyme immunoassay.

Eichler's Hypothesis

Hosts belonging to a large taxonomic group will harbour a greater diversity of parasites than hosts belonging to a smaller systematic group.

Eicosanoids

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *eikosakis* = 20 times.

Eimeria Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

The genus was named honoring Professor Eimer (1843–1897), Tübingen, Germany.

Geographic Distributions/Epidemiology

Worldwide; some species may introduce epidemics in young hosts (e.g., chickens, cattle) which are kept very close together in stables.

Morphology/Life Cycle

The life cycle of the *Eimeria* species (Table 1) mainly runs inside the intestine of plant feeders (e.g., chickens, ruminants, and rodents) and in some few omnivores (e.g., pigs) and is diagrammatically depicted in Fig. 1. Infectious stages are the oocysts, which are excreted unsporulated (Fig. 2a) and which developed outside of the body, four sporocysts each containing two sporozoites (Figs. 2b and 3). If such “sporulated” oocysts are ingested by a specific host – the *Eimeria* species are extremely host specific – the sporozoites enter the cells of the host’s intestine and start within a parasitophorous vacuole their life cycle (Figs. 4 and 5).

For details, see:

- (A) ► *Eimeria* species of ruminants
- (B) *Eimeria suis*
- (C) *Eimeria leuckarti* of equids
- (D) ► *Eimeria* species of birds
- (E) ► *Eimeria* species of rabbits
- (F) ► *Eimeria* species of fish and relatives

Eimeria Species of Ruminants

Name

The genus name honors Professor Theodor ► *Eimer* (1843–1897). Species names are related to towns (e.g., Auburn), to their shapes (e.g., *ellipsoidalis*), to names of scientists (e.g., Nina Kohl-Yakimov, Stieda, Danilov, etc.), or to names of animals (e.g., *bos* = cattle).

Geographic Distributions/Epidemiology

Worldwide; some species may introduce epidemics among young animals in the same stable. Often very high prevalence rates (~80 %) are found in farmed animals.

Morphology/Life Cycle

For each host group (cattle, sheep, and goats), always around 10 specific species have been described, which appear morphologically different and are also different with respect to their

pathogenicity. However, in many cases, the exact species determination remains difficult. Their life cycle runs in principle like that of the *Eimeria* species being depicted in Fig. 6 of the keyword ► *Eimeria*; however, the site of parasitism or the number of schizogonies, etc. may vary considerably. The following species are common and/or very pathogenic: **Cattle** – *E. bovis*, *E. auburnensis*, *E. zuernii*, and *E. ellipsoidalis*; **Sheep** – *E. faurei*, *E. intricata*, *E. ovina*, and *E. ovinoidalis*; and **Goat** – *E. arloingi*, *E. ninakohlyakimovae*, and *E. christensenii*. They all proceed their development intracellularly inside the typical final host (i.e., they are host specific), and their infectious stages (oocysts) are excreted unsporulated.

Symptoms of Disease (Coccidiosis)

This disease (see ► *Coccidiosis, Animals*) affects mainly young animals, while elder ones develop immunity. Typical symptoms are bloody diarrheas due to destruction of the epithelia and underlying cells inclusively blood vessels. Since the diarrhea may be very voluminous, often exsiccosis may occur. Bacterial superinfections may increase the severity of the symptoms. In case of severe infections, the following symptoms occur besides diarrheas: fever, tetanic cramps, and bloody feces, and especially in young animals, high mortality rates are common. In **cattle**, hemorrhagic typhlitis and colitis are common in infections with *E. bovis* and *E. zuernii*, while *E. alabamensis*, *E. auburnensis*, and *E. ellipsoidalis* introduce catarrhal enteritis. In the case of **sheep**, *E. ovinoidalis* leads to hemorrhagic enteritis, while *E. fauri* often introduces the symptoms of a catarrhal enteritis.

Diagnosis

Microscopical analysis of the oocysts after concentration with the help of the ► *flotation* method.

Infection

Oral uptake of sporulated oocysts.

Prophylaxis

Since the oocysts are excreted unsporulated, the regular cleaning of stables from feces is

Eimeria Species, Table 1 Important species of the genus *Eimeria*

Eimeria Species, Fig. 1 Life cycle of *Eimeria* sp. in chicken. For species and other hosts, see Table 1. 1 After oral uptake of sporulated oocysts, the sporozoites hatch in the small intestine from the sporocysts. 2–6 After

penetration, multinucleate ►schizonts are formed (3) inside a ►parasitophorous vacuole (PV). The schizonts produce motile ►merozoites (DM, M). 7 Formation of multinucleate microgamonts, which develop many

very helpful to avoid infections with infectious (sporulated) oocysts. This cleaning should be done with hot steam and/or by use of commercial disinfectants (e.g., Lysococ[®], Club-TV Anticoc[®], P3 Jucicoc[®], etc.) In some countries, also anticoccidial food additions are allowed (e.g., monensin-Na) at doses of 10–30 mg/kg food for cattle, lambs, and goats – when not being used for milk production. However, use of chemical prophylactic products is expensive

and thus often not done. Therefore, it is very important to observe the farmed animals and to start treatment as early as possible in cases of observed infections.

Incubation Period

The timing is species specific and also depends on the amount of ingested oocysts; however, symptoms of disease mostly start within 1 week after infection.

E

Eimeria Species,

Fig. 2 Light micrograph of unsporulated (a) and a sporulated (b) oocysts of *Eimeria tenella* from chicken

Eimeria Species, Fig. 1 (continued) flagellated ► **microgametes** (7.1–7.2). 8 Formation of uninucleate macrogamonts, which grow to be macrogametes (8.1) that are characterized by the occurrence of two types of ► **wall-forming bodies** (WF 1, WF 2). 9 After fertilization, the young ► **zygote** forms the ► **oocyst** wall by consecutive fusion of both types of wall-forming bodies (WF). 10 Unsporulated oocysts are set free via feces (exceptions are reptile- and fish-parasitizing *Eimeria* spp.). 11–13 ► **Sporulation** (outside the host) is temperature-dependent and leads to formation of four sporocysts, each containing

two sporozoites (SP), which are released when the ► **oocyst** is ingested by the next host. DG developing ► **microgametes**, DM developing ► **merozoite**, DW developing wall-forming bodies, FW fusion of WF 1 to form the outer layer of OW, M merozoites, N nucleus, NH nucleus of host cell, OW oocyst wall, PB polar body (granule), PV ► **parasitophorous vacuole**, R refractile (reserve) body, SB ► **sporoblast**, SP ► **sporozoite**, SPC ► **sporocyst**, SPO sporont, WF 1 wall-forming bodies I, WF 2 wall-forming bodies II, Z ► **cytoplasm** of zygote (young oocyst)

Eimeria Species, Fig. 3 Diagrammatic representation of a sporulated oocyst of the genus *Eimeria* containing four sporocysts with two sporozoites each. *AW* outer layer of the wall of the oocyst, *IW* inner layer of the wall of the oocyst, *MK* cap of micropyle, *N* nucleus, *PK* polar body, *RK* refractile body, *RO* residual body of the oocyst, *RS* residual body of the sporocyst, *S* sporocyst, *SP* sporozoite, *ST* Stieda body, *SST* substieda body

Prepatent Period

Species specific: 6–35 days.

Patency

A few weeks.

Therapy

The use of medicaments to control coccidiosis is regulated by national health authorities. Thus, many compounds are not available everywhere. Cattle, sheep, and goats may be treated by ► [toltrazuril](#), sulfonamides, or combination preparations (see ► [Coccidiocidal drugs](#)).

Eimeria and *Isospora* Species of Pigs

See ► [Coccidia](#) of swine.

Eimeria Species, Fig. 4 Light micrograph of the bloody ceca of a chicken infected with *Eimeria tenella*

Eimeria (Synonym, *Globidium*) *leuckarti* of Equids

Name

The genus name *Eimeria* honors Prof. Dr. Theodor ► [Eimer](#) (1843–1897). The species name honors Prof. Dr. Leuckart (1822–1898).

Geographic Distributions/Epidemiology

Worldwide, due to horse transportations all over the world. In Central Europe, up to 80 % of the foals may be infected.

Morphology/Life Cycle

E. leuckarti is the only *Eimeria* species in equids. The oocysts are rather large (70–90 µm × 50–69 µm) characterized by an extremely thick (8–10 µm) and outer oocyst wall and a smooth inner one (Fig. 3). The schizogony and gamogony proceed in cells of the intestinal wall. Schizogony was found in epithelial cells, while gamogony was documented in cells of the lamina propria. Sporulation time outside of the body takes about 2 weeks.

Eimeria Species, Fig. 5 Diagrammatic representation of the sites of infection of *Eimeria* species in chicken intestine. (a) *E. acervulina*, (b) *E. brunetti*, (c) *E. hagani*, (d)

E. maxima, (e) *E. mivati*, (f) *E. mitis*, (g) *E. necatrix*, (h) *E. praecox*, (i) *E. tenella*. B cecum, C colon, D duodenum; P pylorus; Z jejunum (shortened)

Symptoms of Disease

Mostly no or only low-grade symptoms of disease occur. However, young or diseased horses, camels, etc. may suffer from diarrheas. Foals start to excrete oocysts from days 28 until 190; afterward, only rare cases of disease occur.

Diagnosis

Microscopical demonstration of the typical oocysts obtained by use of ► [concentration methods of feces](#) (► [flotation](#); S.A.F.). Since these oocysts are very heavy, it is needed to centrifuge the flotation medium for 7–8 min.

Infection

Oral via contaminated food or drinking water.

Prophylaxis

Regular cleaning of the stables with the help of hot steam and use of disinfectants.

Incubation Period

Two to three weeks (after experimental infections).

Prepatent Period

Rather long: 28–37 days in young animals.

Patency

Three to four weeks.

Therapy

Toltrazuril; however, treatment is only needed in case of symptoms of disease.

Eimeria Species, Fig. 6 Light micrographs (a, b) and scanning electron micrograph (c) of oocysts of *Eimeria leuckarti*. (a) Intact oocyst. (b) The outer oocyst wall is ruptured, thus making visible the inner oocyst wall. (c)

These SEM-micrographs gives an impression of the outer surface of the oocyst wall. A rupture in the outer layer of the oocyst wall, DS thick outer oocyst wall, VE dorsal depression of the outer oocyst wall (site of rupture)

Eimeria Species and Related Coccidia of Birds

Name

The genus name *Eimeria* honors the Swiss-born Professor Theodor ► [Eimer](#) (1843–1897). The species names honor scientists, describe host names, refer to their outer appearance, or are given according to their location in hosts.

Geographic Distributions/Epidemiology

Worldwide; outbreaks in large breeding facilities may reach the status of local epidemics.

Morphology/Life Cycle

The life cycle is diagrammatically depicted in Fig. 1. Some species of farmed animals are very pathogenic and thus they are of huge economic importance. A broad spectrum of host-specific *Eimeria* species occur in the different birds (Figs. 4, 5 and 7).

Chicken

Many species are described; some of them produce significant and often severe pathogenic effects: *E. acervulina*, *E. mitis* (anterior small intestine), *E. brunetti* (ileum and rectum), and *E. tenella* (ceca) (Figs. 4 and 5) *E. mivati* and *E. hagani* are of low pathogenicity and *E. praecox* is even described as apathogenic.

Geese

Pathogenic species are *E. anseris* and *E. nocens* (small intestine and colon), *E. truncata* (in kidney epithelium), and *E. kohlani* (rectum, cloaca).

Ducks

E. kohlani, *E. danailovi*, *Tyzzeria perniciososa* (small intestine), and *E. adenoides* are the most pathogenic species in the posterior regions of the small intestine (ileum) but also in the ceca and colon.

Eimeria Species, Fig. 7 Light micrographs of infected chicken intestines. (a) *E. acervulina*. (b) *E. maxima*

Pigeons

E. labbeana and *E. columbarum* (in the mid region of the small intestine) are both pathogenic.

Parrots

E. dunsigni (in the small intestine) – this species is pathogenic, but occurs only rarely in farmed birds.

Symptoms of Disease (Coccidiosis, Coccidiasis)

Characteristic symptoms of an **acute coccidiosis** are severe, sometimes bloody, diarrheas based on catarrhal or hemorrhagic enteritis. The feces appear watery fluid, contain slimy or bloody elements, or appear yellowish-greenish. High mortality rates occur in some species (e.g., *E. tenella*; Fig. 4); thus, an outbreak of a coccidiosis may lead to enormous economic losses (Fig. 8).

Diagnosis

Microscopical determination of oocysts in the feces after use of ► [flotation](#) method.

Infection

Oral uptake of sporulated oocysts with contaminated food or drinking water.

Prophylaxis

- (a) **Hygienic measurements:** Regular cleaning of cages or soil/floors from feces. Protect drinking water from fecal contaminations. Disinfect stables, floors, and cages with the help of registered disinfectants. **Important:** Use always the **all in-all out** principle for stables

with farmed birds, i.e., take always all animals out of a stable after a period of egg laying or a period of fattening; clean equipment and floors and then enter all new birds at once. Never add single birds to a stable with healthy animals.

- (b) **Chemoprophylaxis:** The basics of this method is to feed permanently small, but efficient amounts of ► [coccidiocidal drugs](#). This method, however, may introduce resistances against several coccidiocidal medicaments.
- (c) **Immunization:** There exist several vaccines (containing attenuated, low-grade pathogenic oocysts); however, many of them are only registered in a certain number of countries (e.g., Coccivac[®], Paracox[®], Livacox[®], etc.). The problem is that these strains may recover their full pathogenicity after some periods of use.

Incubation Period

Three to five days depending on the number of ingested oocysts and the grade of the pathogenicity of the ingested *Eimeria* species.

Prepatent Period

The different *Eimeria* species need different periods until oocysts appear in feces:

- (a) **Chickens:** 4 days (*E. praecox*, *E. acervulina*, *E. mitis*, *E. mivati*); 5 days (*E. maxima*, *E. brunetti*, *E. tenella*); 6 days (*E. necatrix*).
- (b) **Turkeys:** 4 days (*E. dispersa*); 5 days (*E. meleagritidis*, *E. adenoeides*).
- (c) **Geese:** 5 days (*E. truncata*); 7 days (*E. anseris*); 9 days (*E. nocens*).

Eimeria Species, Fig. 8 Light micrographs of intestinal protozoans of ruminants. (a) Cyst of *Giardia* sp. (b) Oocysts of *Cryptosporidium* species. (c–f) *Eimeria* oocysts: (c) *E. granulosus* in fresh sheep feces, (d) *E. ovina* from sheep, sporulated stage, (e) *E. bovis*, unsporulated stage from fresh feces of cattle, and (f)

E. intricata – sporulated oocyst from sheep feces with its characteristic thick wall (for details of each species, see ► [Eimeria](#), Table 1). CW cyst wall, MP micropyle, N nucleus, OW oocyst wall, RB residual body, S sporozoite; SP sporocyst, Z zygote cytoplasm

- (d) **Ducks:** 6 days (*E. perniciosa*); 8 days (*E. danilovi*).
- (e) **Pigeons:** 6 days (*E. labbeana*).
- (f) **Parrots:** 5 days (*E. dunsigni*).

Patency

Mostly rather short (1–3 weeks); however, also slight infections had been reported to occur for months (due to repeated self-infections).

Therapy

Against many of the “older” anticoccidial compounds, resistances have been developed. Thus, the products based on toltrazuril (e.g., Baycox® 15–20 mg/kg bodyweight in drinking water) are

widely used. For further information, see ► [Coccidiocidal Drugs](#) and Table 2.

Eimeria Species of Rabbits

Name

The genus name *Eimeria* honors the Swiss-born Prof. Dr. Theodor ► [Eimer](#) (1843–1897). The species name describes activities (e.g., Latin: *perforans*, penetrating) and sites of infections (e.g., Latin: *intestinalis*, inside the intestine) or honors scientists (e.g., Christian Stieda, 1837–1918).

Geographic Distributions/Epidemiology

Worldwide; in farmed animals small epidemics may occur.

Eimeria Species, Table 2 Food additions in chicken food to avoid coccidiosis

Chemical name	Trade name	Producer	Animals (maximum age)	Dose (ppm) (waiting time)
Meticlorpindol	Coyden [®]	Dow	Fattened hen, keets	125 (5 days)
Decoquinate	Deccox [®]	Rhône-Poulenc (May and Baker)	Fattened hen	20–40 (3 days)
Monensin-Natrium	Elancoban [®] (Coban)	Elanco (Eli Lilly)	Fattened hen young chicken (16 weeks), turkeys (16 weeks)	100–125 (3 days) 100–120 90–100 (3 days)
Robenidine	Cycostat [®]	Cyanamid	Fattened hen, turkeys	30–36 (5 days)
Lasalocid-Natrium	Avatec [®]	Roche	Fattened hen, young chicken (16 weeks), turkeys (12 weeks)	75–125 (5 days) 90–125 (5 days)
Narasin	Monteban [®]	Elanco (Eli Lilly)	Fattened hen	60–70 (3 days)
Salinomycin-Na	Sacox [®]	Hoechst	Fattened hen	50–70 (5 days)
Nicarbazin	Altek [®] 25	MSD	Fattened chicken (4 weeks)	100–125 (9 days)
Maduramicin-ammonium	Cygro [®]	Cyanamid	Fattened hen	5 (7 days)
Narasin/nicarbazin granula 1:1	Maxiban [®]	Elanco (Eli Lilly)	Fattened hen	80–100 (7 days)
Diclazuril	Clinacox [®]	Janssen	Fattened hen	1 (5 days)

Morphology/Life Cycle

The members of the Lagomorpha are parasitized by a large number of *Eimeria* species, which mostly enter the epithelial cells of the small intestine. However, *E. stiedae* (Fig. 9) which parasitizes in liver cells of **rabbits** is one of the most important pathogens. *E. intestinalis*, *E. perforans*, and *E. magna* infect also rabbits and are very pathogenic. *E. contorta* and *E. nieschulzi* are found in **rats**, whereas *E. falciparum* and *E. ferrisi* parasitize in **mice** (e.g., laboratory mouse: *Mus musculus*).

Symptoms of Disease (Rabbits)

- Intestinal coccidiosis** leads to severe diarrheas combined with anemia, extreme weakness, and loss of weight. The effects of these infections are mostly increased by bacterial superinfections leading to high mortality rates.
- Liver coccidiosis of rabbits** is initiated by *Eimeria stiedae*. Main symptoms are liver dysfunctions (loss of activity) and appearance of yellow-whitish nodes in and on the liver

(Fig. 10) and destruction of the parasitized epithelia of the excreting channels of the gall bladder system.

Diagnosis

Microscopical inspection of the fecally excreted oocysts with the help of concentration methods (e.g., ► [flotation](#)).

Infection

Oral uptake of sporulated oocysts with contaminated food or drinking water.

Prophylaxis

Regular cleaning of the cages. Avoidance to add new animals into an existing system without previous isolation (= quarantine) of newcomers.

Incubation Period

Mostly less than 1 week.

Prepatent Period

Species specific: 9–12 days (*E. intestinalis*); 12–14 days (*E. stiedae*).

Eimeria Species, Fig. 9 Light micrographs of unsporulated and sporulated *E. stiedae* oocysts. *MP* micropore, *OW* oocyst wall, *SP* sporocyst

Eimeria Species, Fig. 10 Liver of an *Eimeria stiedae*-infected liver

Patency

Mostly 2–5 weeks, with highest excretion rates during the first and second week of patency.

Therapy

Toltrazuril (Baycox[®]), 25 ppm in drinking water for 2 days; repetition after 5 days.

Eimeriosis

Intestinal infection of many plant eaters due to oocysts of the genus ► *Eimeria* (Fig. 1); the disease is also named coccidiosis (► *Coccidiosis*, Animals).

Elaeophoriasis, Elaeophorosis

Elaeophora (► *Filariidae*) infects deer, elk, and sheep. The adult parasites live in the common carotid and internal maxillary arteries and produce microfilariae which are found in the capillaries of the face and the head. In sheep the ► *microfilaria* induce a granulomatous reaction in the capillaries of the skin, and a dermatitis. The lesions on the head, feet, and abdomen are characterized by intense ► *pruritus* resulting in erythema, ► *alopecia*, excoriations, ulcerations, crusts, and haemorrhage. Stomatitis, rhinitis, and keratitis also occur.

Therapy

Nematocidal Drugs, Animals.

Elaphostrongylosis

Name

Greek: *elaphos* = red deer; *strongylos* = cylindric, and Latin: *cervus* = red deer. Disease of deer or

other ruminants due to infections with the 5–6 cm long (females) or the 3–4 cm long (males) of *E. cervi*. ► *Lungworms*.

Elenia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of Pentastomidae belonging to the group of Porocephalidae.

Elephant Skin

Heinz Mehlhorn

Appearance of horny skin of cattle due to infection with ► *Besnoitia besnoiti*.

Elephantiasis Tropica

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Filariidae; Filariasis, Lymphatic, Tropical; Lymphatic Filariasis; *Wuchereria*, *Brugia*

Main Clinical Symptoms

Lymphangitis, unfeelingness of skin portions; later: chylurie, elephantiasis, i.e., giant swelling of organs (Figs. 1 and 2).

Incubation Period

Three to sixteen months.

Prepatent Period

Seven to twenty four months.

Patent Period

Eight to ten years (adults live for 18–20 years).

Elephantiasis Tropica, Fig. 1 Giant breasts due to Elephantiasis tropica (Photos: O. Dempwolff in: Grüntzig and Mehlhorn (2010) Expeditions into the Empire of plagues, Düsseldorf University Press)

Embryonic and Perinatal Symptoms of Parasitic Infections

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The following table lists possible infections and damages of human embryos and new-born children (See Table 1).

Embryonic and Perinatal Symptoms of Parasitic Infections, Table 1

Parasitic species	Intrauterine damages		Perinatal infections
	1st trimenon	2nd, 3rd trimenon	
<i>Acanthamoeba</i> species	—	Connatal infections seem possible	Connatal infections seem possible
<i>Alaria</i> species Metacercariae	—	—	Infections via mother's milk
<i>Ancylostoma duodenale</i>	—	Diaplacental transmission, anemia risk	Infections via mother's milk
<i>Ascaris lumbricoides</i>	?	In case of bile duct infections abortus risk; eosinophilic pneumonia	Ascariasis of the new-born
<i>Babesia</i> species	—	Connatal babesiosis	Connatal babesiosis
<i>Balamuthia mandrillaris</i>	—	Due to hematogenous spreading, infections are not excluded	?
<i>Blastocystis hominis</i>	—	—	Diarrhea of the new-born
<i>Cryptosporidium</i> species	—	—	Diarrhea and reduced growth of the new-born
<i>Cyclospora cayetanensis</i>	—	—	Diarrhea of the new-born
<i>Entamoeba histolytica</i>	—	Anemia of the mother, reduced growth of the fetus, evtl. early birth	Potential amoebic infection of the new-born
<i>Enterobius vermicularis</i>	Abortus, infection of the embryo	Adnexal-abscess, peritonitis	?
<i>Giardia</i> species	—	—	Giardiasis of the newborn
<i>Leishmania donovani</i> , <i>L. infantum</i>	?	Connatal Kala Azar	?
<i>Naegleria fowleri</i>	Since mothers mostly die, fetus will not survive	Diaplacental transmission does apparently not occur	—
<i>Necator americanus</i>	—	Anemia risk	Transmission via mothers' milk
<i>Onchocerca volvulus</i>	?	Microfilariae enter the fetus	?
<i>Plasmodium falciparum</i>	Connatal malaria	Connatal malaria	Connatal malaria
<i>Plasmodium malarial</i> , <i>Plasmodium vivax</i>	Connatal malaria	Connatal malaria	Connatal malaria, thrombocytopenia
<i>Sarcoptes scabiei</i>	—	—	Generalized scabies of the new-born
<i>Schistosoma</i> species	Sterility, placentitis, low body weight at birth, late abortus	Placentitis	—

(continued)

Embryonic and Perinatal Symptoms of Parasitic Infections, Table 1 (continued)

Parasitic species	Intrauterine damages		Perinatal infections
	1st trimenon	2nd, 3rd trimenon	
<i>Strongyloides fuelleborni</i> , <i>S. stercoralis</i>	–	–	Transmission via mother’s milk
<i>Taenia solium</i>	–	–	Neurocysticercosis of the new-born
<i>Toxocara canis</i>	No diaplacental transmission	Increased risk of abortion	–
<i>Toxoplasma gondii</i>	Abortion, hydrocephalus internus, cysts, neurologic dysfunction, blindness	Connatal toxoplasmosis, retardation, hydrocephalus, chorioretinitis, hepatosplenomegalia, thrombocytopenia, cramps	Generalized infection: hepatitis, myocarditis, pneumonia
<i>Trichinella spiralis</i>	?	Diaplacental transmission into the fetus	–
<i>Trichomonas vaginalis</i>	–	Premature birth, retards growth	Trichomoniasis or new-born girls, newborn pneumonia, neonatal breathing problems
<i>Trichuris trichiura</i>	–	Anemia	–
African <i>Trypanosoma</i> species	?	Rare cases of connatal sleeping sickness: hydrocephalus, meningoencephalitis	?
<i>Trypanosoma cruzi</i>	Abortion	Chorioamnionitis, premature birth, liver, spleen swelling, neurological disorders, heart problems, death	Connatal Chagas disease?
<i>Wuchereria bancrofti</i>	?	Microfilariae enter fetus	?

? = suspected, but not proven

Embryophore

Thick wall surrounding the larva (► [Oncosphaera](#)) of ► [cestodes](#) inside eggs. Since in several tapeworm eggs the outer eggshell is smooth and becomes ruptured, the

embryophore is the only cover to protect the larva (e.g., ► [Taenia](#), ► [Echinococcus](#)).

Emesma

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek term for vomited material, which in the case of dogs and cats may contain living worms of the genus ► [Toxocara](#).

Emetine

Alkaloid out of *Cephalis ipecacuana* being used against amoebiasis or as vomitory means.

Empodium

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *en* = on; *pous, podos* = foot.
This term describes a structure at the tarsus of arthropods.

Encephalitis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *encephalon* = brain; *itis* = disease.
This term describes an inflammation of the brain, e.g., by transmitted viruses.

Encephalitozoon

Name

Greek: *en* = into, *kephale* = head, *zoon* = animal.

Classification

Genus of ► [Microspora](#).

Important Species

Table 1.

Life Cycle

Figures 1, 2 (pp 450, 451).

Disease

► [Encephalitozoonosis](#).

Encephalitozoon, Table 1 Important species of the genus *Encephalitazoon*

Species	Host	Habitat	Size of spore (µm)	Geographic distribution
<i>Encephalitozoon lacertae</i>	Lizards (<i>Podarcis</i> sp.)	Epithelium of intestine	3.5 × 1.5	France
<i>E. cuniculi</i>	Rabbits, rats, mice <i>Mastomys</i> spp., guinea pigs, hamsters, goats, sheep, dogs, foxes, felids, mustelidae, monkeys, humans	Intestine + many organs; tissue cultures	2.5 × 1.5	Worldwide
<i>E. helleri</i>	Humans (AIDS)	Many organs	2.4 × 1.5	Worldwide
<i>E. intestinalis</i>	Humans (AIDS)	Many organs	2.0 × 1.5	Worldwide

Encephalitozoon, Fig. 1 Life cycle of *Encephalitozoon cuniculi*, which may parasitize within a variety of hosts including immune depressive humans. 1 The infection of AIDS patients occurs via oral uptake of spores that derive from urine of animals (via contaminated food or via touching of furs). The mature uninuclear spore is characterized by five windings of the polar tube (1) and the occurrence of a posterior vacuole (P). 2, 3 In human intestine the spore extrudes the polar tube being injected into a host cell. The uninuclear sporoplasm creeps

through the tube in the cytoplasm of the host cell, where it is included within a parasitophorous vacuole. 4, 5 Reproduction by repeated binary fissions. The last binary fission (5) leads to 2 uninuclear sporoblasts, which each grow up and differentiate into an infectious cyst. The latter are freed when the host cell is used up and bursts. Thus these spores may become distributed in the whole body or set free in human stool. HC, host cell; N, nucleus; NH, nucleus of host cell; P, posterior vacuole; W, windings of the polar tube; T, polar tube

Encephalitozoon, Fig. 2 Giemsa-stained blood smear showing enlarged human monocytes filled with large amounts of sporoblasts of *Encephalitozoon* sp. (courtesy Professor Dr. Heydorn, Berlin)

Encephalitozoon cuniculi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *encephalon* = brain; *zoon* = animal; *cuniculus* = rabbit.

Geographic Distribution/Epidemiology

Several hundred thousands of immunosuppressed humans are infected worldwide up to 80 % by wild rabbits.

Morphology/Life Cycle

The spores of this species measure $2.5 \times 1.5 \mu\text{m}$. They infect a broad spectrum of hosts (see Table 1) parasitizing the intestine and kidneys but also several other organs and the brain (especially in AIDS patients). The life cycle is depicted diagrammatically in Fig. 1 and other related species in Table 1.

Symptoms of Disease

Encephalitozoons: In the case of rodents, the symptoms are mild and remain mostly at a chronic

stage. However, infected carnivores, monkeys, and humans (especially children and AIDS patients) are severely diseased. The latter may develop a so-called **encephalitis-nephritis syndrome**, which often leads to death. In addition, severe damages may occur in the eye, where lesions are formed in the arteries.

Diagnosis

Microscopical determination of spores in probes of urine or feces. Histological sections show stages of this species when colored with methenamine silver, HE, or Gram stain. Blood smears show monocytes being filled with sporoblasts (Fig. 2). Serological techniques (IFAT, KBR, ELISA, etc.) show only 70 % of de facto existing infections.

Infection

Oral, mostly by oral uptake of wind-drifted spores from urine or feces or by ingesting contaminated food or water. In cases of animals, also congenital and diaplacental infections may occur.

Prophylaxis

Avoid oral contact with pet animals (hamsters, rabbits, dogs, etc.). Exert hygiene measurements in contact with spoiled urine or fecal remnants.

Incubation Period

One week.

Prepatent Period

Variable.

Patency

Unknown in immunocompetent hosts, months in untreated immunosuppressed hosts.

Encephalitozoon cuniculi, Table 1 Important species of the genus *Encephalitozoon*

Species	Host	Habitat	Size of spore	Geographic distribution
<i>Encephalitozoon lacerate</i>	Lizards (<i>Podarcis</i> sp.)	Epithelium of the intestine	3.5 × 1.5	France
<i>E. cuniculi</i>	Rabbits, rats, mice, <i>Mastomys</i> spp., guinea pigs, hamsters, goats, sheep, dogs, foxes, felids, Mustelidae, monkeys, humans (AIDS)	Intestine + many organs, tissue cultures	2.5 × 1.5	Worldwide
<i>E. helleri</i>	Humans (AIDS)	Many organs	2.4 × 1.5	Worldwide
<i>E. intestinalis</i>	Humans (AIDS)	Many organs	2 × 1.5	Worldwide

E

Encephalitozoon cuniculi, Fig. 1 Life cycle of *Encephalitozoon cuniculi*, which occurs in several animal species (see Table 1) and in humans. (1) The infection starts by oral uptake of spores within fecally contaminated food or water. (2, 3) Inside the host, the polar tube is extruded and injected into an intestinal host cell. The uninuclear sporoplasm creeps into the cytoplasm of the host cell and is enclosed there in a parasitophorous vacuole

(3). (4) Reproduction occurs by binary fission. (5) Due to repeated binary fissions, finally binucleated stages (sporonts) are formed in the parasitophorous vacuole. The nuclei fuse and a uninuclear sporont is formed, which grows up and develops into the spore by formation of a protecting wall (1). HC host cell, N nucleus, NH nucleus of the host cell, P posterior vacuole, T tubelike polar filament, W five windings of the polar filament (tube)

Treatment

Unknown. Tests of immunosuppressed mice showed that benzimidazoles, chloroquine, and

oxytetracyclines reduced the production of spores for about 60 days. Albendazole and metronidazole have also diminishing effects on cyst numbers for a short time when given

Encephalitozoon cuniculi, Fig. 2 Giemsa-stained blood smear showing enlarged human monocytes filled with large amounts of sporoblasts of *E. cuniculi* (courtesy Prof. Dr. Heydorn, Berlin)

2 × 400 mg/day for 21 days. Cyclosporine, however, was fully ineffective.

Encephalitozoonosis

Synonyms

Microsporidiosis, Encephalitozooniasis

General Information

Encephalitozoonosis is a nervous system disease caused by the obligate intracellular microsporidian ► *Encephalitozoon cuniculi*. The disease has been

described in rodents, lagomorphs, primates, and several species of carnivores. Asymptomatic infection usually occurs in rodents and lagomorphs. In carnivores the neurological signs include repeated turning and circling movements, especially after disturbance, dysmetria, dysergia, blindness, and a terminal semi-comatose state. Lesions described are ► [encephalitis](#) and segmental vasculitis. The course of the illness is usually 5–12 days. This parasite is also found in immunodeficient people as pathogen with a generalized spreading over many organs (► [Opportunistic Agents](#)).

Therapy

- [Treatment of Opportunistic Agents](#), see also
- [Drugs Against Microsporidiosis](#).

Encystation

Process found in many parasitic protozoans which involves formation of a ► [cyst wall](#) either outside or inside the ► [cell membrane](#). Worm stages may also become encysted to survive inside or outside hosts.

Endectocides

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes pharmaceutical compounds with endoparasitological and ectoparasitological activities. Avermectins (e.g., ► [ivermectin](#)) belong to the most developed class of endectocides being developed as a 16-membered ring of macrocyclic lactones by fermentation from an actinomycete (fungus). Ivermectin itself is a semisynthetic avermectin derivative being first licensed in 1981 for veterinary use. It was detected by the Japanese scientist ► [Omura](#) from ► [Kitasato University](#) at Tokyo, who got the Nobel Prize for Medicine and Physiology in the year 2015.

Endemic Zone

► **Geographic Zones of Occurrence of Diseases:** infections are always present.

Endemicity

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In case of planned eradication programs, it is needed to define the endemic status of target diseases in a given region. For malaria endemicity definition, the year prevalence rates of the parasites among children aged between 2 and 10 years were used to establish the following groups:

- Hypoendemicity: less than 10 % of children are infected.
- Mesoendemic: 11–50 % are infected.
- Hyperendemic: 51–75 % are infected.
- Holoendemic: more than 75 % are infected.

Endemy

From *Greek*: endon = inside, demos = people. Persistent occurrence of parasites/agents of disease in a defined region.

Endocytic Apparatus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

From Greek *endon* = inside; *kytos* = cell.

Endocytosis is a special form of phagocytosis and is used to take up a broad spectrum of needed foreign (host derived) or own products (e.g., variant surface antigenic material – VSG = variant surface glycoproteins). In the case of trypanosomes, it was shown that the flagellar pocket, where the single flagellum is anchored, is the exclusive site for endocytic activity, which in trypanosomes is clathrin mediated. VSG can be rapidly taken up there by the endocytic system and – when recycled inside – brought back onto the cell surface. The high speed of endocytosis observed there allows quick removal and subsequent inner degradation of surface-bound antibodies and thus guarantees survival of these parasites inside the bloodstream of their hosts by the help of their efficient recycling of an intact VSG coat.

Endocytosis

In addition to the direct transport of molecules through the ► **cell membrane** (► **Membrane Transport**), other mechanisms exist for internalization of materials by cells. For example,

Endocytosis, Fig. 1 (a–g) Transmission electron micrographs of feeding systems in protozoans. (a) Dorsal endocytosis in *Giardia lamblia* ($\times 10,000$). (b) General phagocytosis in *Trichomonas vaginalis* ($\times 8000$). (c–e) Micropore in erythrocytic stages of *Hepatozoon aegypti* (C $\times 7000$), *Plasmodium falciparum* (D $\times 22,000$), and *Theileria annulata* (E $\times 44,000$). (f) Micropore in a cross-sectioned cyst *Besnoitia jellisoni* from mice. Acid phosphatase activity was shown in

mitochondria ($\times 25,000$). (g) Cell mouth (*Cytostome*) in a ciliate ($\times 500$). A, amylopectin; AX, axoneme; CI, cilia; CY, cytostome; EN, enigmatic body; ER, endoplasmic reticulum; FV, food vacuole; GO, Golgi apparatus; MA, macronucleus; MI, mitochondrion; MN, microneme; MP, micropore; MT, microtubule; MV, microvilli of intestinal host cell; N, nucleus; NM, nuclear membrane; RE, remnants of erythrocyte; VD, ventral disk

Endocytosis, Fig. 2 Diagrammatic representation of a sporozoan micropore in longitudinal and tangential sections. *E*, possible enlargement of the cytostomal invagination; *FU*, filamentous elements; *IM*, inner membrane of the ► **pellicle**; *INI*, interruption of IM (forms outer ring in tangential section); *INO*, densification along the inner ring (formed by the invaginated outer membrane); *MM*, middle membrane of the pellicle; *OM*, outer membrane of the pellicle; *SR*, solid densification between IM and MM

relatively large organic materials may be internalized by endocytosis, i.e., by the formation of endocytotic vesicles. This process is termed ► **pinocytosis** for the uptake of liquids and phagocytosis for the uptake of solid particles. Within the ► **vacuoles** the material is degraded and then transported into the ► **cytoplasm** by mechanisms similar to those used by the cell membrane. Alternatively, it may be released by dissolution of the membrane. Some ► **Protozoa** have developed special places for the uptake of food, called cytostomes (Fig. 1). Endocytosis may occur at any point on the cell membrane (Fig. 1b) or is restricted to predisposed places. For example, in *Giardia* ► **trophozoites**, endocytosis occurs only in the dorsal region, the region opposite the ventral sucker, which is the site of attachment (Fig. 1a); in trypanosomes, endocytosis occurs in the ► **flagellar pocket** (► **Pellicle**, Fig. 2E); and in sporozoans it is found at small cytostomes called ► **micropores** (Figs. 1c–f). While motile stages

such as merozoites and sporozoites possess only one micropore, gamonts, schizonts, and/or growing stages develop several such ► **cytostomes** due to their need of a quick uptake of nutrients. Large endocytotic elements (cytostomes or cell mouths) are characteristic of many ciliates, too (Fig. 1g). Cytostomes may be reinforced by various structures, for instance by bundles of microtubules in trypanosomes and ciliates or by cylinder-like structures in coccidians (Figs. 1c, 2). After the phagosomes have entered the cytoplasm, the contents are digested and resorption of the necessary molecules occurs. The residue may be voided to the outside (► **Exocytosis**) or stored as an inclusion.

Many cells contain clathrin-coated pits that are involved in the receptor-mediated endocytosis of macromolecules, but our knowledge of ► **coated pits** in Protozoa remains limited.

Endodyogeny

A peculiar longitudinal division of those ► **Coccidia** (e.g., *Toxoplasma*, ► *Sarcocystis*) that form tissue-cysts (Cell Multiplication).

Endoparasite

Organism living parasitically within another animal or man.

Endoparasites of Humans

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Some important human endoparasites are listed in Table 1 (in alphabetical order).

Endoparasites of Humans, Table 1

Species	Human cases ^a	Stage used for diagnosis	Inter-human transmission ^b	Incubation period ^c (days)	Prepatency period ^d (weeks)	Patency (weeks) ^e	Prophylaxis ^f	Treatment ^g	Other/additional therapies ^h
<i>Acanthamoeba</i> spp.	Hundred thousands	<i>Acanthamoeba</i> liquor	+	2–14	<1	<3 or lethal	No bathing in contaminated rivers/lakes	Amphotericin B + sulfadiazine (or tetracycline)	Keratitis: neomycin, clotrimazole
<i>Acanthocheilonema</i> (<i>Dipetalonema</i>) <i>persians</i>	50–60 million	Microfilariae	–	120	16–52	>52	Avoid bites of insects	Diethylcarbamazine	Antiallergic drugs
<i>Ancylostoma duodenale</i>	500 million	Eggs/feces	Free larvae +	14–28	5–7	~1000	Use of shoes	Albendazole, mebendazole, pyrantel pamoate	Antianemic measurements
<i>A. braziliensis</i> , <i>A. caninum</i>	Many thousands	Migrating	Larvae	1–3	0	0	Use of shoes	Tiabendazole	?
<i>Angiostrongylus cantonensis</i>	Many thousands	Larvae/liquor	–	7–21	0 (no adults)	Larvae: months	No raw food	Tiabendazole	?
<i>Angiostrongylus costaricensis</i>	Many thousands	Eggs/biopsy of intestinal wall	–	1–4	3–4	>52	No raw snails	Tiabendazole, ivermectin	?
<i>Anisakis</i> spp.	Thousands	Eggs/biopsy of intestinal wall	–	1 h – 7 days	0	Larvae: weeks	No raw fish	?	Surgical removal
<i>Armillifer armillatus</i>	Many thousands	Larvae/biopsy	–	?	0	0	Avoid feces of snakes	?	Surgical removal
<i>Ascaris</i> spp.	1.2 billion	Eggs/feces	+	4–7	6–11	>52	Avoid green salad, feces of pigs	Mebendazole, albendazole	?
<i>Babesia</i> spp.	Some thousands	Merozoites/blood smear	–	5–28	1	50	Avoid tick bites	Clindamycin, chinine	Blood exchange
<i>Balantidium coli</i>	Many thousands	Veg. stages/feces	+	4–14	<1	>20	Avoid pig feces	Metronidazole, nitroimidazoles	Tetracyclines, paromomycin
<i>Blastocystis hominis</i>	30–40 million	Cysts/veg. stages	+	1–3 ?	<1	2–3	Avoid feces	Metronidazole, cotrimoxazole	Substitution of electrolytes
<i>Brugia malayi</i> , <i>B. timori</i>	100 million	Microfilariae/blood	–	84–400	52	1000	Avoid bites of mosquitoes	Macrofilariae + microfilariae: diethylcarbamazine	Antiallergic drugs
<i>Capillaria hepatica</i>	Few	Eggs/liver biopsy	–	?	?	Larvae: 50–100	Avoid green salad	Tiabendazole	?
<i>Capillaria philippinensis</i>	Thousands	Eggs/larvae/feces	+	?	?	?	Avoid green salad	Mebendazole, tiabendazole	?
<i>Cercarial dermatitis</i>	Hundred thousands	Cercariae/skin	–	Minutes	0	0	No bathing in contaminated water	Antiallergic compounds	?

<i>Clonorchis sinensis</i>	30–30 million	Eggs/feces	–	14	2–3	~1000	Avoid raw fish	Praziquantel	?
Creeping eruption	Many thousands	Migrating/ larvae/biopsy	–	1–3	Larvae: weeks	Larvae: weeks	?	Tiabendazole	Icing, surgical removal
<i>Cryptosporidium</i> spp.	Hundred thousands	Oocysts/ feces	+	1–12	2–4	1–2 up to 52	Avoid feces	?	Substitution of electrolytes
<i>Cyclospora</i> spp.	Thousands	Oocysts/ feces	+	2–7	1	2–9	Avoid human feces	Cotrimoxazole	?
<i>Cysticercus cellulosae</i>	Hundred thousands	Cysticercus/ serology/CT	Eggs of adult tapeworm	70–90	0	0	Avoid human feces	Praziquantel, albendazole	Symptomatic; mechanical removal
<i>Demodex folliculorum</i>	Many millions	Skin probe	+	14	2	Years	Avoid contact with infected animals	Hexachlorocyclohexane, ivermectin (10 %), neem	Symptomatic therapy
<i>Dicrocoelium dendriticum</i>	Thousands	Egg/feces	–	14–28	7–8	>250	Avoid unwashed green salad	Praziquantel	?
<i>Diocotylus renale</i>	Few thousands	Egg/urine	–	30	12–24	150	Avoid raw fish	?	Mechanical removal
<i>Dipetalonema perstans</i>	50–60 million	Microfilariae/ blood	–	120	>36	>52	Avoid bites of insects	Diethylcarbamazine	Antiallergic compounds
<i>Dipetalonema streptocerca</i>	4–10 million	Microfilariae/ skin	–	120	>52	>52	Avoid bites of insects	Diethylcarbamazine	Antiallergic compounds
<i>Diphyllobothrium latum</i>	13–5 million	Proglottids/ eggs/feces	–	>21	3	520	Avoid raw fish	Niclosamide, praziquantel	Substitution of vitamins
<i>Dipylidium caninum</i>	Many thousands	Proglottids/ feces	–	10–21	2–3	52	Avoid fleas	Niclosamide, praziquantel	Protect pets against fleas
<i>Dirofilaria</i> spp.	Thousands	Larvae/ biopsy	–	90–270	28	Larvae: years	Avoid bites of insects	Diethylcarbamazine	Surgical removal
<i>Dracunculus medinensis</i>	10 million	Adult worm/ skin	–	90–200	40–56	♀ dies days after excretion of larvae	Avoid uncooked water	Mebendazole, tiabendazole	Remove worm from skin
<i>Echinococcus granulosus</i>	Hundred thousands	Cyst/CT/ biopsy	–	>360	Years	Years	Avoid dog feces	Mebendazole, albendazole	Surgical removal of cyst
<i>Echinococcus multilocularis</i>	Thousands	Cyst/CT	–	>360	Years	Years	Avoid fox, dog feces	Mebendazole, albendazole	Do not touch the cyst
<i>Echinostoma ilocanum</i>	Thousands	Egg/feces	–	?	3	?	Avoid uncooked snails	Praziquantel	?

(continued)

Endoparasites of Humans, Table 1 (continued)

Species	Human cases ^a	Stage used for diagnosis	Inter-human transmission ^b	Incubation period ^c (days)	Prepatency period ^d (weeks)	Patency (weeks) ^e	Prophylaxis ^f	Treatment ^g	Other/additional therapies ^h
<i>Encephalitozoon cuniculi</i>	Hundred thousands	Spore/urine	+	7	?	?	Avoid human urine	Chloroquine, oxytetracycline, albendazole	?
<i>Entamoeba histolytica</i> (a) Intestinal stages	400–500 million	Cyst/feces	+	2–21	>1	Years	Avoid any uncooked food/human feces	Diloxanide furoate, nimorazole, paromomycin, 8-hydroxyquinoline	Antibiotics (tetracyclines, erythromycin)
		<i>Amoebae</i> /biopsy/CT/endoscopy/sonography	–	2–28, up to years	1–2	Years/recidives		Metronidazole, tinidazole, ornidazole, dehydroemetine	Remove fluid from the liver abscess
(b) Tissue stages									
<i>Enterobius vermicularis</i>	1.2 billion	Eggs/anal groove	+	7–28	4–5	9–12	Clean anal region	Mebendazole, albendazole, pyrantel pamoate	Repeat treatment at least two times in 3-week intervals
<i>Enterocytozoon bienersi</i>	Thousands	Spore/feces	+	7	1	20	Avoid human feces	Albendazole	?
<i>Enteromonas hominis</i>	200 million	Veg. stages/feces	+	?	?	?	Avoid feces	Not needed	?
<i>Fannia</i> species (flies)	Thousands	Larvae/urine	–	–	0	0	Keep skin clean	Mechanical remove	Clean urine bladder
<i>Fasciola hepatica</i>	Thousands	Egg/feces	–	21–90	8–13	>250	Avoid eating plants from cow meadow	Dehydroemetine, praziquantel	?
<i>Fasciolopsis buski</i>	15–20 million	Egg/feces	–	21–90	9–14	>250	Avoid eating of chestnuts	Niclosamide, praziquantel	?
Fly larvae	Hundred thousands	Larvae/biopsy	–	2–10	0	0	Keep skin clean	Mechanical removal	Use antibiotics
<i>Gastrodriscoides hominis</i>	Thousands	Egg/feces	–	21–90	9–14	>250	Avoid eating water plants	Niclosamide, praziquantel	?
<i>Giardia lamblia</i>	450 million	Cyst/feces	+	3–21	3–4	Years	Avoid human/dog feces	Tinidazole, metronidazole, ornidazole, nimorazole	Reduce uptake of carbohydrates
<i>Gnathostoma spinigerum</i>	Thousands	Larvae/biopsy	–	?	0	100	Avoid raw fish	Albendazole	Corticosteroids
<i>Haemonchus</i> spp.	Few	Egg/feces	+ via free larvae	28–35	12–24	>52	Avoid contaminated plants	Tiabendazole, mebendazole, albendazole	?

<i>Hartmannella</i> spp.	see <i>Acanthamoeba</i> (synonym)								
<i>Heterophyes heterophyes</i>	10 million	Egg/feces	–	7–21	1–3	24–40	Avoid raw fish	Praziquantel	?
<i>Hymenolepis diminuta</i>	Thousands	Eggs/proglottids/feces	–	7–14	2	8–12	Avoid larvae in beetles	Niclosamide, praziquantel	?
<i>Hymenolepis nana</i>	75 million	Eggs/proglottids/feces	+	7–28	4	2–50	Avoid self-infection	Niclosamide, praziquantel	?
<i>Isospora belli</i>	Hundred thousands	Oocyst/feces	+	2–13	1	4–7	Avoid human feces	Sulfonamides	?
<i>Lamblia (Giardia) intestinalis</i>	Old name for <i>Giardia lamblia</i>								
<i>Leishmania braziliensis</i>	10–15 million	Veg. stage/skin smear	–	14–21 up to 1 year	1	Years	Avoid bites of sand flies	Amphotericin B, antimony (V) compounds, metronidazole, pentamidine	Antibiotics, sulfonamides
<i>Leishmania donovani</i> , <i>L. chagasi</i> , <i>L. Infantum</i>	20–40 million	Veg. stage/smeer	–	10–120	1–3	>52	Avoid bites of sand flies	Pentamidine, antimony (V) compounds, diamidine	Support immune system
<i>Leishmania tropica</i> group	60 million	Veg. stage/skin scrape	–	14–21	1–3	40	Avoid bites of sand flies	Sodium stibogluconate	Antibiotics, sulfonamides
<i>Linguatula serrata</i>	Few	(a) Egg/saliva (b) Larvae/biopsy	+(eggs)	a/b 5–10	(a) 3 at ♀ (b) 0 at larvae	(a) 50–100 at ♀ (b) 0 at larvae	Avoid raw meat	?	Mechanical removal
<i>Loa loa</i>	40 million	Microfilariae/blood	–	60–360	52–200	17 years	Avoid bites of tabanids	Diethylcarbamazine	Mechanical removal of adults
<i>Macracanthorhynchus hirudinaceus</i>	Many hundred thousands	Larvae/intestinal biopsy	–	14–80	0	No adults	Do not eat raw insects	Loperamide	Surgical removal
<i>Malaria</i> agents	see <i>Plasmodium</i> spp.								
<i>Mansonella</i> species	see <i>Dipetalonema</i> spp.								
<i>Mansonella ozzardi</i>	12–15 million	Microfilariae/blood	–	?	?	?	Avoid bites of insects	Diethylcarbamazine	
<i>Metagonimus yokogawai</i>	Hundred thousands	Egg/feces	–	?	?	?	Avoid raw fish	Praziquantel	
<i>Metorchis conjunctus</i>	Thousands	Egg/feces	–	?	4–5	250	Avoid raw fish	Praziquantel	
<i>Microsporidia</i>	see <i>Encephalitozoon</i> sp. and <i>Enterocytozoon bieneusi</i>								
<i>Myiasis</i> agents (fly larvae)	Hundred thousands	Larvae/biopsy	–	10–14	Larvae: 5–10	Larvae: 5–10	Use of repellents	Subcutaneously, symptomatic eye: 1 % mintacol	Mechanical removal

Endophagic

► **Mosquitoes** (e.g., *Anopheles gambiae*, the principal vector of ► **malaria** in Africa) that bite predominantly indoors (rooms, buildings).

Endoplasm

The dense central part of the ► **cytoplasm** which contains the cell organelles and the nucleus.

Endoplasmatic Reticulum

The endoplasmic reticulum (ER) is a large system of tubes and sacs that runs throughout the cell. It connects the perinuclear space with the cell interior and with the cell surface. There are 2 types of ER: rough ER (rER) and smooth ER (sER). The rER is characterized by the presence of ► **ribosomes** (► **Pellicle**, Fig. 1B, ► **Trichomonadida**, Fig. 1C) along its outer surface, whereas these are lacking in the sER. The rER and the sER may be interconnected.

Endosulfan

Chemical Class

Organohalogenide (organochlorine compound, cyclodiene).

Mode of Action

GABA-gated chloride channel antagonist.
► **Ectoparasitocides – Antagonists and Modulators of Chloride Channels.**

Endosymbiosis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This process has its name from Greek: *endom* = inside and *symbiosis* = together living and describes that one organism lives inside another. This permanent coexistence, which supports both organisms, is common among the recent species on earth (e.g., algae live in the cells of corals). In the case of the ► **Apicomplexa** (e.g., species of the genera *Toxoplasma*, ► *Sarcocystis*, ► *Eimeria*, ► *Isospora*, ► *Plasmodium*), even a secondary endosymbiosis occurs, since the so-called ► **apicoplast** represents a former red algae cell that had previously ingested another cell (*Cyanobacterium*), which is now retained as so-called chloroplast in its interior.

This endosymbiosis (double or single) is considered as the driving force in eukaryotic evolution.

Bioenergetics

General Information

The generation of chemical energy for the cell (usually in the form of ATP) can be accomplished by either aerobic or anaerobic strategies. Aerobic generation of energy is defined as the complete oxidation of substrates to carbon dioxide and water via the combined action of the tricarboxylic acid (TCA) cycle and a mitochondrial respiratory chain. In this pathway, in which oxygen acts as the final electron acceptor to reoxidize reduced coenzymes, the major portion of ATP is produced by a process known as oxidative phosphorylation. In parasitic protozoa and helminths, the occurrence of this conventional type of energy metabolism is rather limited. It is mainly the free-living and some larval stages of helminths that are supposed to possess a functional TCA cycle and an aerobic mitochondrial respiratory system. A special category of organisms are the trypanosomatids, such as the bloodstream form of *Trypanosoma brucei*, whose energy metabolism is dependent on a plantlike alternative terminal oxidase. These organisms use oxygen as terminal electron acceptor, but this oxidative process via the alternative oxidase is not coupled to phosphorylation. Most parasites use, in the stages inside their hosts some kind of fermentation process for the production of ATP. Fermentations are defined as energy generating processes that produce their own oxidants to balance the production and consumption of coenzymes (NADH) without the use of oxygen as final electron acceptor. In some cases, this strategy is linked to an electron transport chain and oxidative phosphorylation (anaerobic “respiration”). Suitable substrates for fermentations are carbohydrates,

because both oxidation and reduction of these compounds can occur, which is not possible using fatty acids as substrate. During lactate or ethanol producing fermentations these redox reactions are accomplished in the linear process of glycolysis. An alternative strategy, which is widely found in helminths involves a branched pathway (malate dismutation), in which a portion of the substrate is oxidized while another portion is reduced. Fermentations are widespread in endoparasites and are the sole or major ATP-producing routes in many protozoan and adult helminth parasites.

In all living cells, nutrient molecules are broken down to provide the energy required for the generation of ATP. This ATP can be synthesized from ADP via two basically different processes: substrate-level phosphorylation and oxidative phosphorylation. Substrate-level phosphorylation is the formation of ATP by the direct phosphorylation of ADP via the transfer of a phosphoryl group from a high-energy intermediate to ADP. Oxidative phosphorylation is the process in which ATP is formed when electrons are transferred from the reduced coenzymes NADH or FADH₂ to oxygen via a series of electron carriers that make up the mitochondrial electron transport chain (also called respiratory chain). NADH and FADH₂ (produced in glycolysis, fatty acid oxidation, and the TCA cycle, from NAD⁺ and FAD, respectively) are energy-rich compounds. They contain high-energy electrons obtained from metabolic intermediates. Transfer of these electrons from the reduced coenzymes to oxygen releases a large amount of free-energy that can be used to produce ATP. The transport of electrons through the electron transport chain leads to the pumping of protons across the mitochondrial inner membrane by three electron-driven proton pumps: NADH-ubiquinone reductase (Complex I), cytochrome reductase (Complex III), and cytochrome oxidase (Complex IV). The resulting proton gradient across the inner mitochondrial membrane is then used for the generation of ATP when electrons flow back into the mitochondrial matrix via ATP synthase. Oxidative phosphorylation provides most of the energy in aerobically functioning parasites, but is also connected to malate dismutation, the anaerobic fermentation variant

operative in most adult helminths, where instead of oxygen, fumarate acts as terminal electron acceptor of the electron transport chain.

Inhibitors of the electron transport chain are often used to study the energy metabolism of parasites. These compounds bind to a component of the chain and block the flow of electrons, which results in a decreased ATP production, as electron transport and energy production are tightly coupled. Examples of frequently used inhibitors are: rotenone and amytal (inhibitors of Complex I), antimycin A (an inhibitor of electron flow through Complex III), and cyanide, azide, or carbon monoxide (inhibitors of Complex IV). Oligomycin and other unrelated compounds block the proton channel of the ATP-synthase, thereby directly inhibiting ATP synthesis. As some components of the electron-transport chain in parasites are often structurally slightly different from those in their hosts, the electron transport chain is also a suitable target of antiparasitic drugs. The antimalarial drug atovaquone, for instance, acts on complex III of the electron transport chain of *Plasmodium*; ascofuranone is a potent inhibitor of the alternative oxidase of trypanosomes, and nafuredin shows selective inhibition of complex I in helminth mitochondria.

In the energy metabolism of endoparasites, several biochemical reactions exist which have either no parallel in other eukaryotes or are a result of a modification of rather universal pathways. The energy metabolism of endoparasites is a fascinating and extensively studied research area of parasite biochemistry. Its vital function and divergence from that of their hosts makes the energy metabolism of parasites an interesting target for antiparasitic drug design.

Closely related to bioenergetics is the function of molecular oxygen in living organisms. Most of the oxygen consumed by animal cells is utilized by the cytochrome oxidase-linked mitochondrial respiration. In many parasitic protozoa and helminths this metabolic capability often does not exist or is considerably reduced. On the other hand, many endoparasites unequivocally have an aerobic requirement, if not for energy generation, then for specialized oxidative reactions such as eggshell tanning in helminths. These other

functions of oxygen vary greatly between different species and their developmental stages, and have not yet been very well studied.

Adaptations

The major functions of the metabolism of animals are (1) to catabolize organic substances and to couple these processes to the conservation of chemical energy; (2) to assemble distinct, low-molecular weight precursors that are derived either directly from external sources or via metabolic interconversion of absorbed nutrient molecules into species-specific polymeric components (nucleic acids, proteins, polysaccharides, and lipids); and (3) to form and degrade the biomolecules required in specialized functions. Endoparasites are no exception to this universal concept but obviously, as a consequence of their parasitic way of life, they have evolved a variety of specific modifications, extensions, or simplifications to the metabolic pattern observed in most other forms of life.

As in many habitats, the major nutritional requirements for parasites are supplied by the host. Many synthetic pathways in parasites were abandoned during their evolution. These reduced biosynthetic capabilities have resulted in the elaboration of efficient mechanisms for substrate absorption and in specific pathways for interconversion and modification of substrate molecules. Additional features relate to the sophisticated adaptive mechanisms which enable parasites to evade the host's immune response and other defense systems. In many cases, unique metabolic structures and processes are maintained by parasites to cope with the extreme physical and chemical conditions often prevailing within their host environments. Still other metabolic peculiarities may be related to the distinct morphological organization of parasites, such as the lack of a circulatory system in helminths or the absence of a digestive tract in cestodes. Next to the adaptations in metabolism related to their opportunistic way of living as a parasite, helminths show a second type of adaptations, i.e., those connected to the environmental changes that occur in their life

cycle. During their complex developmental cycles, these organisms live alternating periods as free-living and parasitic stages. Usually, the free-living stages cannot obtain substrates from the environment. They have to live on the endogenous reserves that they obtained in their previous host. In the environment of parasitic stages, on the other hand, substrates are plentiful, and their only concern is to produce offspring and avoid being destroyed by the host's immune system. These changes in the environmental conditions are accompanied by metabolic adaptations. Unusual adaptive processes are found particularly in the strategies of energy metabolism, in the various routes of purine and pyrimidine salvage, and in the synthesis of numerous other molecular structures serving specialized functions.

Kinetoplastid Flagellates

The energy metabolism of kinetoplastid flagellates is better characterized than that of any other group of protozoan parasites. Most of the knowledge of the bioenergetics in these organisms has derived from studies on *Trypanosoma brucei*, *T. cruzi*, and a few *Leishmania* spp. This work has uncovered a variety of metabolic properties unique to the kinetoplastids, although large differences in metabolism also exist between the different species and stages of these organisms.

The long slender bloodstream trypomastigotes of *T. brucei* rely entirely on glycolysis for their energy production, with pyruvate being the sole end product (Fig. 1). In this pathway one molecule of glucose is converted to two molecules of pyruvate with a net synthesis of two molecules of ATP. Glucose is first degraded to 3-phosphoglycerate within membrane-bounded microbody-like organelles, called glycosomes, that are unique to the order Kinetoplastida. The 3-phosphoglycerate formed is then further degraded in the cytosol to pyruvate. Unlike in anaerobic lactate fermentation, in which the reducing equivalents generated by glyceraldehyde 3-phosphate oxidation are finally transferred to pyruvate (resulting in the formation of lactate), in *T. brucei* molecular oxygen serves as terminal

electron acceptor, resulting in the formation of water as catalyzed by a plantlike alternative oxidase that is present in the inner membrane of the trypanosome's single mitochondrion (Fig. 1).

All of the glycolytic enzymes necessary to convert glucose into 3-phosphoglycerate are localized within the glycosomes (Fig. 1). These organelles, that are related to the peroxisomes in other eukaryotes, are unique to the trypanosomatid flagellates, such as *Trypanosoma*, *Leishmania*, *Phytomonas* and *Crithidia*. Glycosomes are bounded by a single membrane, extremely homogeneous in size, measure about 0.3 μm in diameter and represent more than 4 % of the total cell volume. In *T. brucei*, more than 200 glycosomes are present per organism while in other genera these organelles are not as abundant.

The possible functional advantage of the extreme subcellular compartmentation and enzyme association within the trypanosome cell is still debated. About 90 % of the glycosomal protein content consists of glycolytic enzymes which appear to be in close association. Originally it was suggested that compartmentalization of glycolysis in the glycosome enables the parasite to sustain its high rate of glycolysis because of the high concentration of substrates and enzymes which provided some kind of channeling in the pathway. There is, however, no experimental evidence for metabolite channeling in trypanosomes. Furthermore, calculations performed during modelling of glycolysis in bloodstream trypanosomes indicated that compartmentation of the enzymes in glycosomes is not necessary to obtain the observed glycolytic flux. Even if the glycolytic enzymes were not sequestered in a single compartment, diffusion should not be controlling the glycolytic flux in *T. brucei*. In addition, *T. brucei* indeed has a fairly high glycolytic flux when compared to mammalian tissues, but similar and even higher fluxes are also observed in other microorganisms, which do not possess glycosomes. Furthermore, all kinetoplastids possess glycosomes, including those that are not solely dependent on glycolysis for energy generation. Recent kinetic modelling suggested that concentrating the enzymes in glycosomes protects the trypanosome from phosphate depletion or

Energy Metabolism, Fig. 1 Schematic representation of pathways involved in carbohydrate and amino acid metabolism in bloodstream (left panel) and procyclic (right panel) form *Trypanosoma brucei*. Substrates are shown in ovals and end products in boxes. The shaded broad arrows in the background of the TCA-cycle represent functions of those parts of the cycle that are active in procyclic forms. The dark-shaded arrow indicates the flux from pyruvate and oxaloacetate to citrate in the transport of acetyl-CoA units from the mitochondrion to the cytosol, the intermediate shaded one represents that part of the

cycle that is used for the degradation of proline and glutamate to succinate, whereas the lightly shaded one indicates the part of the cycle that is used during glyconeogenesis. Of the glycerol-3-phosphate shuttle only the components are shown and the travel of dihydroxyacetonephosphate and glycerol-3-phosphate between the glycosomes and the mitochondrion is not shown. AA, amino acid; AOX, plant-like alternative oxidase; CI, II, III, and IV, complex I, II, III, and IV of the respiratory chain; c, cytochrome c; FAS, fatty-acyl synthesis; Glu, glutamate; α-KG, α-ketoglutarate; OA, oxoacid; PPP, pentose phosphate pathway; Q, ubiquinone

osmotic shock caused by an unrestricted accumulation of sugar phosphates, and that it protects the cell from a failure to recover from glucose deprivation. Glycosomal metabolism is also involved in CO₂ fixation and in the biosynthesis of purine and pyrimidine nucleotides and ether-lipids.

Under anaerobic conditions, bloodstream trypomastigotes convert glucose to equimolar amounts of pyruvate and glycerol (Fig. 1). Under these circumstances, high concentrations of glycerol 3-phosphate and ADP are expected to accumulate inside the glycosomes. This allows

the glycerol kinase (which is present in extremely high specific activities in trypanosomes capable of producing glycerol under anaerobiosis) to proceed in the unusual direction of ATP formation. As shown in Fig. 1, anaerobic glycolysis yields 1 ATP per glucose, via pyruvate kinase, but this is apparently not sufficient for growth. Incubation of bloodstream form *T. brucei* under anaerobic conditions leads to cell death, while attempts to knock out the alternative oxidase were unsuccessful and a 95 % depletion of the alternative oxidase by RNAi led to a serious growth defect.

Transformation of bloodstream form *T. brucei* into the procyclic insect stage is accompanied by striking changes in energy metabolism (Fig. 1). Upon transformation into the procyclic insect stage, the glycosomal metabolism is extended, and part of the produced phosphoenolpyruvate is imported from the cytosol and subsequently converted into succinate via phosphoenolpyruvate carboxykinase, malate dehydrogenase, fumarase, and a soluble glycosomal NADH:fumarate reductase. Furthermore, in this procyclic insect stage the end product of glycolysis, pyruvate, is not excreted but is further metabolized inside the mitochondrion, in which it is mainly degraded to acetate. Acetate production occurs by acetate:succinate CoA-transferase and involves a succinate/succinyl-CoA cycle that generates extra ATP. Surprisingly, under all conditions studied so far, the TCA cycle does not function as a cycle in procyclic *T. brucei* for the complete oxidation of acetyl-CoA to carbon dioxide. It was shown that parts of the TCA-cycle machinery are used in other processes, such as partial degradation of amino acids, but also for biosynthetic purposes, such as fatty acid biosynthesis and gluconeogenesis (Fig. 1). In addition to carbohydrate degradation amino acids, mainly proline and threonine, are thus important substrates for the production of ATP in procyclic insect stage *T. brucei*. Utilization of amino acids correlates well with the change in the trypanosome's environment. Under resting conditions, proline is present in tsetse hemolymph in excessively high concentrations, and the midgut of the fly is deficient in carbohydrates but rich in amino acids and peptides.

The reducing equivalents (NADH), generated by substrate oxidation, are in all trypanosomatids delivered to a respiratory chain that uses oxygen as the final electron acceptor, but essential differences in respiratory chains exist among the various species and developmental stages. The long-slender bloodstream stage of *T. brucei* lacks cytochromes and a classical respiratory chain, but contains instead a plantlike alternative oxidase. Reducing equivalents produced in the glycosomes are transferred to the mitochondrion via the classical mammalian-type glycerol 3-phosphate/dihydroxyacetone phosphate shuttle (Fig. 1). The mitochondrial FAD-linked glycerol-3-phosphate dehydrogenase donates electrons to the ubiquinone/ubiquinol pool, and the reduced ubiquinol is then the electron donor for the alternative oxidase. This process of electron transfer via the alternative oxidase is not linked to ATP production, does not involve cytochromes, is insensitive to cyanide and antiycin A, but is susceptible to inhibition by aromatic hydroxamic acids like salicylhydroxamate (SHAM) and the antifungal agents ascofuranone and miconazole.

The procyclic insect stages of trypanosomes, in contrast, possess not only the alternative oxidase system, but also a classical, cyanide-sensitive cytochrome-containing respiratory chain, coupled to oxidative phosphorylation (Fig. 1). Apart from complex I, this part of the respiratory chain of trypanosomatids strongly resembles the mammalian type respiratory chain, as no dissimilarities have been found yet. It is unknown yet, what physiological advantage the multiple oxidase assembly may offer to trypanosomes. Under the conditions of the midgut of the tsetse fly where oxygen concentrations are low, expression of the alternative oxidase system would be downregulated, but the cytochrome *aa₃*-linked respiratory chain would be induced and become functionally operative. As the latter system is coupled to oxidative phosphorylation, the economic efficiency of the overall energy generating metabolism of procyclic trypanosome stages would by far exceed that of the bloodstream forms. This would well reflect the environmental transition from the vertebrate blood with its abundant supply of nutrients and oxygen to the insect

midgut, where limited substrate and oxygen concentrations may have forced the parasite to develop a more efficiently functioning and versatile energy-generating system. Intermediate and short stumpy bloodstream forms of *T. brucei* have better-developed mitochondria than the long-slender forms and are not dependent only on glycolysis for energy generation. Apparently, the transition in energy metabolism between the glycolysis-dependent long-slender form and the mitochondrion-dependent procyclics occurs already in the bloodstream. The transitional bloodstream forms are thus pre-adapted to functioning in the insect vector if ingested with a blood meal. Substrate availability and/or energy metabolism seem to have a function in the induction of differentiation processes during the trypanosomal life cycle, but the underlying mechanisms are not yet fully understood.

The substrates and metabolic pathways utilized for energy generation by other kinetoplastids are similar to those observed in the procyclic culture forms of *T. brucei*. The differences in energy metabolism between the two main morphological forms of *Leishmania* spp. are less pronounced than those of *T. brucei*. The glycolytic enzymes are present in glycosomes, and the cristate mitochondria of *Leishmania* possess TCA-cycle enzymes and a cytochrome-oxidase-linked respiratory chain, just like *T. brucei*. The relative importance of carbohydrates and amino acids as an energy source is not completely clear, however, and may vary with the stages, species, and phase of growth.

Leishmania promastigotes have an energy metabolism in which a small part of the carbohydrate is completely oxidized to carbon dioxide via the TCA cycle, but in which large amounts of partly oxidized products, like acetate, pyruvate and succinate, are also produced as end-products of glucose metabolism. A small part of the pyruvate is transaminated to alanine, which is then excreted. In *Leishmania* promastigotes, the partly oxidized end products are the result of an aerobic metabolism involving an electron-transport chain, with oxygen as final electron acceptor, as in procyclic trypanosomes. *Leishmania* promastigotes, like the insect stage of *T. brucei*, have a classical

respiratory chain but lack the alternative oxidase that is present in the other Trypanosomatidae. *Leishmania* promastigotes are strongly dependent on this classical respiratory chain for their energy generation, which is in agreement with the observation that *Leishmania* promastigotes possess an energy metabolism in which most of the carbohydrate is degraded to partially oxidized end products, a process concomitantly producing NADH that is reoxidized by the respiratory chain.

Leishmania amastigotes most likely have an energy metabolism very similar to that of the promastigotes, both stages being dependent on TCA-cycle activity and a mammalian-type respiratory chain, although fatty acids probably are a more important substrate in the insect stage, at least in *L. mexicana*. This would correlate with the nutritional conditions of their intracellular habitat, the macrophage, in which a sufficient supply of lipids is likely to be available.

The energy metabolism of *T. cruzi* strongly resembles that of *Leishmania*, i.e., all stages of this parasite possess TCA-cycle activity and a mammalian-type respiratory chain linked to the generation of ATP. However, like *Leishmania*, *T. cruzi* catabolizes glucose only partially to carbon dioxide and produces, in addition, various organic compounds as metabolic end products, including acetate and succinate.

Anaerobic Protozoa

Protozoan parasites which have been classified as anaerobes occur in the taxonomic groups of trichomonad flagellates, and *Entamoeba* and *Giardia* spp. These organisms differ from most other eukaryotes in that they lack morphologically recognizable mitochondria (amitochondriate) and such biochemical attributes as the tricarboxylic acid cycle, cytochromes, and oxidative phosphorylation. They do not require oxygen for their survival and multiplication, but can tolerate low oxygen concentrations. As a consequence of this metabolic organization, energy generation in these organisms functions anaerobically and is exclusively associated with substrate-level phosphorylations. An important source of energy for

Energy Metabolism, Fig. 2 The pathways of energy metabolism in anaerobic protozoa. 1, PP_i-dependent phosphofructokinase; 2, glycerol-3-phosphate dehydrogenase; 3, glycerol-3-phosphatase; 4, 4 glycolytic enzymes; 5, pyruvate phosphate dikinase (not present in trichomonads); 6, pyruvate kinase; 7, alanine aminotransferase; 8, pyruvate:ferredoxin oxidoreductase; 9, acetate thiokinase (not present in trichomonads); 10, acetyl CoA reductase/alcohol dehydrogenase; 11, hydrogenase; 12, acetate:succinyl CoA transferase; 13, succinyl CoA synthetase. Glycerol formation

occurs only in trichomonads and lactate formation only in *T. vaginalis*. In *Giardia* and *Entamoeba*, acetate formation occurs in the cytosol and is not coupled to hydrogen production. Metabolic end products are boxed. Asterisks indicate sites of ATP formation. *AcCoA*, acetyl coenzyme A; *DHAP*, dihydroxyacetonephosphate; *Fd*, ferredoxin; *F6P*, fructose-6-phosphate; *F-1,6-P2*, fructose-1,6. bisphosphate; *GAP*, glyceraldehyde-3-phosphate; *MAL*, malate; *OAA*, oxalacetate; *PEP*, phosphoenolpyruvate; *PP_i*, pyrophosphate; *PYR*, pyruvate

anaerobic protozoa are carbohydrates which are stored in large amounts in the form of glycogen and degraded via an extended glycolytic pathway to different organic end products and CO₂. On the other hand, these organisms do consume O₂ when it is available, but the mechanism of this oxygen utilization process is unclear (see below).

Recently, mitochondrion-related organelles, called mitosomes, have been identified in a number of amitochondriate parasitic protozoa, including *Entamoeba histolytica*, *Giardia*, *Cryptosporidium parvum*, and microsporidians. Like mitochondria, mitosomes are double-membrane-bounded and contain some mitochondrial-type proteins, including chaperonin 60 (Cpn60), heat shock protein 70 (Hsp70), and the protein machinery responsible for iron-sulfur cluster assembly, but in contrast to mitochondria, mitosomes have not retained an organellar genome. The presence of mitosomes in

parasitic protozoa lacking typical mitochondria provides evidence that these organisms are not primary amitochondriate, but have diverged from other eukaryotes after the mitochondrial endosymbiosis event.

Trichomonad flagellates distinguish from *Entamoeba* and *Giardia* in their ability to eliminate substrate-derived reducing equivalents in the form of molecular hydrogen by a pathway resembling that observed in some anaerobic eubacteria. As illustrated in Fig. 2, catabolism of carbohydrate in these parasites proceeds by classical glycolysis up to the step of pyruvate which is further metabolized to acetate, CO₂, and hydrogen. *Trichomonas vaginalis* and *Tritrichomonas foetus* show the same metabolic pattern, except that the former trichomonad produces lactate and the latter succinate as additional end products. The process of acetate formation in trichomonads is highly

unusual for a eukaryote in that it is achieved by oxidative decarboxylation of pyruvate via a ferredoxin-linked step catalyzed by pyruvate:ferredoxin oxidoreductase. In a subsequent reaction, catalyzed by the iron-sulfur enzyme hydrogenase, the electrons are transferred from ferredoxin to protons to form molecular hydrogen. The ferredoxins involved in pyruvate oxidation of anaerobic protozoa are 12 kDa iron-sulfur proteins that differ in their structural properties among different species. The trichomonad ferredoxin possesses only a [2Fe-2S] cluster similar to mitochondrial iron-sulfur proteins, whereas the ferredoxins of *Entamoeba* and probably *Giardia* contain 2 clusters of 4 iron atoms bound to 4 acid-labile sulfur atoms (2[4Fe-4S]). The characteristic trichomonad ferredoxin-dependent metabolic properties account for the selective toxicity of 5-nitroimidazole antiprotozoal drugs.

Another feature unique to the trichomonads is that the enzymes involved in pyruvate oxidation are carried in a separate organelle, the hydrogenosome, which is bounded by two closely apposed unit membranes and thus represents a metabolic compartment separate from the cytosol. The exact evolutionary position of the hydrogenosome is still debated, but functional and morphological considerations leads to the suggestion that hydrogenosomes and mitochondria are related organelles. The presence of hydrogenosomes is not restricted to trichomonad flagellates since they have been discovered also in anaerobic rumen ciliates, in fungi and in free-living protozoans of anaerobic sediments. The establishment of these organelles appears to be one of the various evolutionary approaches to adapt to an anaerobic mode of life. The advantage achieved with this strategy over that evolved in other anaerobic systems is that substrate-derived reducing equivalents can be directly eliminated in the form of molecular hydrogen and that substrate oxidation beyond the pyruvate step increases the economic efficiency of the energy generating system over that observed in simple lactate or ethanol fermentation. The conversion of acetyl CoA, the primary product of anaerobic pyruvate oxidation in trichomonads, to free acetate can be coupled to substrate-level ATP synthesis, a process catalyzed

by the combined action of two enzymes involving a CoA transferase and succinyl CoA synthetase.

Like trichomonad flagellates, the energy metabolism of *Giardia* and *Entamoeba* is entirely fermentative (Fig. 2), irrespective of whether oxygen is present or not, which is in accordance with the lack of mitochondria and the functions associated with these organelles. The utilization of carbohydrate results in the formation of a mixture of acetate, ethanol, and CO₂. Anaerobically, more ethanol and less acetate are produced, whereas in the presence of oxygen the catabolism switches to produce more acetate. In this pathway, the major fate of glycolytically formed pyruvate is its oxidative decarboxylation to acetyl CoA, catalyzed by an enzyme analogue to the ferredoxin-linked oxidoreductase of trichomonad flagellates. However, unlike trichomonads, *Giardia* and *Entamoeba*, because of the lack of a ferredoxin-linked hydrogenase, are not able to form molecular hydrogen. As an alternative, in these anaerobes reduced ferredoxin is utilized in the formation of ethanol as catalyzed by the bifunctional enzyme, acetyl CoA reductase/alcohol dehydrogenase. Oxygen may also act as terminal acceptor for the reducing equivalents removed from pyruvate, which would explain the aerobic requirement for acetate formation, but the precise steps involved in this pathway of electron flow are still unclear. As in trichomonads, hydrolysis of the acetyl CoA in these parasites can also be linked to energy generation by substrate level phosphorylation, but this step is catalyzed by a single enzyme, a novel type of acetate thiokinase (Fig. 2), which is known to occur only in some prokaryotes.

A notable feature of glycolysis in anaerobic protozoa is its dependency on pyrophosphate (PP_i) as a phosphate donor rather than on adenine nucleotides (Fig. 2). In a first step, a phosphofructokinase (PP_i-PFK) utilizes PP_i to phosphorylate the glycolytic intermediate fructose 6-phosphate to form the corresponding 1,6-bisphosphate. The second PP_i-dependent enzyme, pyruvate phosphate dikinase (PPDK), is located in lower glycolysis, where it replaces the pyruvate kinase (PK). In *T. vaginalis*, only the phosphofructokinase is PP_i-specific, whereas in *Entamoeba* and in *Giardia* both PP_i-PFK and PPDK are present. Recently,

the coexistence of PPDK with PK in *Giardia* and the occurrence of a glycosomal PPDK in addition to cytosolic PK have been reported for *Giardia* and *T. brucei*, respectively. Other parasitic protozoa, including some apicomplexans, were also found to contain PP_i-PFK instead of the corresponding ATP-dependent enzyme, though these species are not considered to be anaerobic. A third PP_i-linked enzyme, phosphoenolpyruvate (PEP) carboxyphosphotransferase, is a constituent of a three-enzyme system functioning in *Entamoeba* as an alternative route for PEP utilization (Fig. 2). In this step, the high-energy phosphate bond of PEP is transformed into a PP_i bond with simultaneous fixation of CO₂. *Entamoeba* appears to be the only eukaryotic cell in which this enzyme is present. The possible physiological roles of inorganic PP_i utilization may be to conserve the energy of the PP_i generated during anabolic processes and, as the PP_i-linked enzymatic reactions are reversible under physiological conditions, they may have functions not only in catabolic but also anabolic routes.

Anaerobic protozoa experience sometimes aerobic conditions within their natural environments and consume oxygen when provided, at rates comparable to those observed for aerobic protozoa and can tolerate surprisingly high concentrations of this gas *in vitro*. *T. vaginalis* has even been shown to grow optimally in the presence of small amounts of oxygen, and therefore these organisms may be classified as microaerophiles rather than anaerobes. Although the trichomonads, *Giardia* and *Entamoeba*, are devoid of any heme-containing proteins, reducing equivalents can be transferred from substrates to molecular oxygen. This reaction is catalyzed by NAD(P)H oxidoreductases which are located in the cytosol and apparently produce water as the reaction product. As an alternative, electrons to oxygen may be also donated through a succession of electron carriers containing flavins, non-heme iron, and other high potential carriers of an unknown nature. The precise architecture and physiological role of these presumptive respiratory systems of anaerobic protozoa, which are not associated with energy generation, remain to be elucidated. The fact that, with the exception of the large intestine, neither

of the tissues colonized by these parasites are notably deficient in oxygen suggests that aerobic processes may be operative *in vivo*, and it was suggested that the respiratory systems may have a role in protecting the cell against oxygen damage.

Apicomplexans

Detailed knowledge of the bioenergetics of apicomplexan protozoa is limited to the intraerythrocytic stages of *Plasmodium* and *Eimeria*, while this aspect in the case of other genera has received only little attention. Generally, carbohydrates serve as the main energy source throughout the life cycle of apicomplexans. The erythrocytic stages of the malarial parasite lack energy stores and, consequently, use blood glucose as the primary nutrient. *Eimeria* spp. and *Toxoplasma gondii* bradyzoites store carbohydrate in the form of amylopectin, a known reserve polysaccharide of plants and some free-living protozoa and rumen ciliates. Like most other endoparasites, apicomplexan protozoa have a limited capacity to oxidize substrates completely to CO₂ and water but instead satisfy their energy requirements by fermentative mechanisms. The erythrocytic forms of mammalian malarial parasites convert glucose almost quantitatively to lactate, regardless of whether oxygen is present or not. Carbohydrate metabolism of the intraerythrocytic stages of *Babesia* seems to parallel that of human malarial parasites in that glucose is primarily or solely degraded to lactate. *Eimeria*, *Toxoplasma*, and *Cryptosporidium* also ferment carbohydrate to lactate with minor formation of acetate and glycerol. In common with anaerobic protozoa, glycolysis of various apicomplexans is unusual in that it contains PP_i-PFK instead of the conventional ATP-dependent enzyme. Another unique feature of these protozoans is that their lactate dehydrogenases, including those of *Plasmodium*, *Eimeria*, and *Toxoplasma*, contain a five-amino-acid insert around the active site, which may explain, at least in part, the unusual specificities of these enzymes in apicomplexans. A common feature of coccidian parasites is also the accumulation of mannitol,

a carbohydrate previously known to be present only in fungi. The presence of mannitol in *Eimeria*, and probably also in *Toxoplasma* and *Cryptosporidium*, is associated with a cyclic pathway (mannitol cycle) that involves a synthetic and catabolic part and is linked to glycolysis via fructose 6-phosphate. The function of mannitol in coccidial parasites is still unclear, but suggested possibilities are its role as an energy reserve or osmoregulator, or it may act as a mechanism for dealing with oxygen radicals.

The lack of a full complement of the tricarboxylic acid cycle (TCA-cycle) enzymes in the apicomplexan parasites investigated has left a classical mitochondrial function involving complete substrate oxidation doubtful. Furthermore, in *Toxoplasma gondii* and *Plasmodium* spp. pyruvate dehydrogenase is only present inside the apicoplasts and not inside the mitochondria. This implies that acetyl-CoA, the substrate for the TCA-cycle, cannot be generated from pyruvate inside the mitochondria. On the other hand, several apicomplexans, notably all life cycle stages of *Eimeria* and *Toxoplasma*, contain distinctive, cristate mitochondria. The presence of various cytochromes have been detected in these parasites and their respiration is sensitive to inhibition by cyanide and other mitochondrial electron transport inhibitors. For *Eimeria* it was suggested that during the processes of sporulation and excystation, which are associated with high respiratory activities, but also within those parasite stages preparing for an extracellular phase of life, a more aerobic type of metabolism may be established using the TCA cycle and cytochrome-linked substrate oxidation. As oxygen is required for optimal growth *in vitro* and inhibitors of respiration have significant effects on the survival of malarial and other apicomplexan parasites, a function of the mitochondrion in a capacity other than energy generation must be crucial. A possible functional significance of respiration in apicomplexans could be its coupling to the pyrimidine biosynthetic pathway as appears to be the case for blood stage *P. falciparum*. The observation that the anticoccidial quinolones and pyridinols inhibit respiration in *Eimeria* sporozoites and oocysts rather selectively suggests major

differences between the coccidial and mammalian type of mitochondrial electron transport systems. Avian malarial parasites seem to have rather different bioenergetic capacities. Their cristate mitochondria appear to possess a functional TCA cycle, and in accordance with these properties, free erythrocytic stages of these species are able to oxidize a significant portion of the carbohydrate utilized to CO₂. *C. parvum* seems to lack mitochondria suggesting that oxygen is unimportant and glycolysis is the major strategy of energy generation in this apicomplexan.

Helminths

Adult Helminths

As substrate for energy conservation the adult stages of most helminths use primarily carbohydrate, of which glycogen is the main storage polysaccharide, consisting in many cases of as much as 10 % of the worm's wet weight. The catabolism of amino acids does not seem to be of particular importance for energy generation with the exception of glutamine, whose co-utilization with carbohydrate was shown to be energetically advantageous for some helminth species. Generally, the bioenergetic pathways found in adult helminths function primarily anaerobically. Effective terminal oxidative processes, such as the TCA cycle and a conventional type of respiratory chain, are very often absent or of limited activity, which precludes the utilization of fatty acids as an energy source. For the same reason, the degradation of carbohydrates and amino acids beyond the acetyl-CoA stage is only hardly feasible. As a consequence, most adult helminths are not capable of oxidizing organic compounds to a significant extent to CO₂ and water. More pronounced oxygen-dependent routes, however, appear to exist in small helminth species and in the outermost tissue layers of larger worms.

Although the pattern of end products varies greatly between different species of adult helminths, none of them degrades carbohydrates completely to carbon dioxide, as the free-living stages do. As helminths in general do not use oxygen as final electron acceptor, they must have

Energy Metabolism, Fig. 3 Generalized pathways of carbohydrate degradation by parasitic helminths. The aerobic metabolism of free-living and larval stages is shown in open arrows and the anaerobic fermentation pathways of adults in closed arrows. End products are in black boxes. *AcCoA*, Acetyl-CoA; *CI*, *III* and *IV*, complex I, III and IV of the respiratory chain; *CITR*, citrate; *FRD*, fumarate reductase; *FUM*, fumarate; *MAL*, malate; *Methylmal-CoA*,

methylmalonyl-CoA; *ME*, malic enzyme; *OXAC*, oxaloacetate; *PEP*, phosphoenolpyruvate; *PEPCK*, phosphoenolpyruvate carboxykinase; *PK*, pyruvate kinase; *PROP*, propionate; *Prop-CoA*, propionyl-CoA; *PYR*, pyruvate; *RQ*, rhodoquinone; *SDH*, succinate dehydrogenase; *SUCC*, succinate; *Succ-CoA*, succinyl-CoA; *UQ*, ubiquinone

a fermentative metabolism instead and excrete organic substances as metabolic end products. When oxygen cannot function as terminal electron acceptor, the degradation of substrates has to be in redox balance. Two approaches are pursued by helminths to fulfil this requirement. Some species, including adult schistosomes and filarial nematodes, use the classical adaptation to anaerobic metabolism by degrading carbohydrates to lactate or ethanol. This so-called anaerobic glycolysis yields two molecules of ATP per molecules of glucose degraded. Although most adult parasites use this strategy to some extent, the majority uses a different approach (malate dismutation), in which carbohydrates are degraded to phosphoenolpyruvate (PEP) via the conventional Emden-

Meyerhof pathway. PEP is then carboxylated by phosphoenolpyruvate carboxykinase (PEPCK) to form oxaloacetate, which is subsequently reduced to malate (Fig. 3). The fate of PEP at the pyruvate kinase/PEPCK branch point will depend on the activity ratios and kinetics of the two enzymes involved, but is also determined by substrate concentrations, the rate of subsequent reactions and other factors. This part of the pathway occurs in the cytosol and is comparable to the formation of lactate or ethanol in being redox balanced and yielding two molecules of ATP per mol of glucose degraded. However, the malate produced in the cytosol is, unlike lactate, not excreted but transported into the mitochondria for further degradation. In a branched pathway, a portion of

malate is oxidized to acetate and another portion of it is reduced to succinate. The oxidation occurs via two consecutive steps of oxidative decarboxylation, first to pyruvate via malic enzyme and subsequently to acetyl CoA via pyruvate dehydrogenase. The pyruvate dehydrogenase complex of *Ascaris suum* was shown to be specifically adapted to anaerobic functioning. The acetyl CoA formed is converted to acetate via a succinate/succinyl-CoA cycle. In the other part of the pathway, reduction of malate occurs in two reactions which reverse part of the TCA-cycle. Many helminths metabolize succinate further to propionate, which is then excreted. This so-called malate dismutation is in redox balance when twice as much propionate is produced as compared to acetate.

Apart from the electron-transport-associated ATP formation in the reduction of fumarate (see below), malate dismutation is also accompanied by substrate-level phosphorylations (Fig. 3). Formation of acetate from acetyl-CoA occurs via two consecutive enzymatic steps with the concomitant production of ATP. The presence of the first enzyme of this reaction, acetate:succinate CoA-transferase, has now been unequivocally demonstrated in *F. hepatica*. The formation of propionate from succinate occurs through a sequence of metabolic reactions required for propionate utilization in animal tissues but working in reverse (Fig. 3). This cyclic pathway involves a set of enzymatic reactions which require deoxyadenosylcobalamin and biotin and accomplish the loss of a carboxyl group as CO₂. Each pass of the sequence promotes the synthesis of one molecule of ATP through coupling of ADP phosphorylation with the decarboxylation of methylmalonyl CoA. In total, the anaerobic production of propionate and acetate yields approximately five molecules of ATP per molecule of glucose degraded.

In the anaerobically functioning mitochondria of helminths capable of malate-dismutation, the electron-transport chain is different from the one present in mammals in that endogenously produced fumarate functions as the terminal electron acceptor instead of oxygen. In this case, electrons are transferred from NADH to fumarate via complex I and fumarate reductase (Fig. 4). Free-living

stages of helminths, however, possess an aerobic energy metabolism with a classical mammalian type respiratory chain (see below). This implies that during the development of free-living into the parasitic stages, a transition occurs from succinate oxidation via succinate dehydrogenase in the TCA cycle to the reverse reaction, reduction of fumarate to succinate. Bacteria contain two homologous but distinct enzyme complexes to catalyse these reactions, one to oxidize succinate (succinate dehydrogenase) and one to reduce fumarate (fumarate reductase). Different enzymes are needed for these two reactions because the electron flow through the two complexes is in opposite direction, which implies differences in the affinity for electrons (standard electron potential) of the electron-binding domains of these enzyme complexes. Distinct enzyme complexes have now also been described in the parasitic nematodes *Haemonchus contortus* and *A. suum*. These complexes were shown to be differentially expressed during the life cycle of the parasites and are suggested to function either as a succinate dehydrogenase or as a fumarate reductase. In addition to customary enzyme complexes for succinate oxidation and fumarate reduction, also distinct quinones are involved in these processes in helminths.

In many helminths, the primary products of anaerobic malate metabolism, acetate, succinate and propionate, accumulate as major excretory products. Some other helminths metabolize these compounds further to branched-chain fatty acids. In *A. suum*, the branched-chain fatty acids, 2-methylbutyrate and 2-methylvalerate, are the predominant end products of anaerobic carbohydrate metabolism. As demonstrated in Fig. 5, these acids arise from the condensation of acetyl CoA with propionyl CoA or of 2 propionyl CoA units, with subsequent conversion of the condensation products to the saturated fatty acids. This pathway is also located inside the anaerobically functioning mitochondrion and is similar to the reversal of β -oxidation of fatty acids, although some of the enzymes involved in branched-chain fatty acid production of helminths differ in their kinetics and regulatory properties from the corresponding mammalian β -oxidation enzymes. There is evidence to

Energy Metabolism, Fig. 5 Formation of branched-chain fatty acids by *Ascaris suum*. (After Komuniecki and Harris (1995)) 1, propionyl condensing enzyme; 2, 2-methyl acetoacyl CoA reductase; 3, 2-methyl-3-oxo-acyl CoA hydratase; 4, 2-methyl branched-chain enoyl CoA reductase; 5, acyl CoA transferase; *ETC*, electron-transport chain (see Fig. 4). The synthesis of 2-methylpentanoate (2-methylvalerate) proceeds in a similar way, except that 2 propionyl CoA units are used in the condensing reaction then

approximately five molecule ATP is produced per mol of glucose catabolized. In spite of the obvious advantage of multiple anaerobic catabolic systems over simple lactate fermentation, the economic efficiencies of these pathways are still very low compared to that obtained from complete substrate oxidation to CO₂ and water, which generates approximately 30 molecules of ATP per molecule glucose degraded.

Free-Living and Larval Stages of Helminths

Most free-living stages of helminths are self-supporting, i.e., they do not obtain food or

substrates other than oxygen from their environment. They are completely dependent on the endogenous food stores that they have obtained in their previous host. Glycogen is present in many free-living stages and is used to span the gap in food supply until the next host is entered. The free-living and parasitic developmental stages of helminths have, unlike the adult parasites, usually an aerobic energy metabolism. Many of them, such as the free-living infective eggs of *A. suum*, eggs and developing larvae of *Nippostrongylus brasiliensis* and *H. contortus*, juvenile liver flukes and young schistosomula, and various free-living cercariae, have a high oxygen requirement, mainly for energy generation, with high TCA-cycle and mitochondrial respiratory chain activities. These organisms thus are capable of completely oxidizing substrate carbon to CO₂ and water. In addition, smaller amounts of oxygen are needed for synthetic purposes, such as the formation of collagen and fatty acid desaturation. Another feature of the developmental stages of helminths is that the diversity of energy sources that can be utilized is, in many cases, greater compared to that of the respective adult forms. For instance, the free-living stages of many parasitic nematodes and some cercariae rely heavily on lipids for their energy generation, implying that a functional β -oxidation sequence is present in these stages. Generally, there is, however, great variation in the oxygen requirements and the capabilities for substrate utilization in the developmental stages of helminths, and the situation in one species may not be necessarily relevant for another species.

If the metabolism of helminths differs between larval and adult stages, then the developmental cycle of these organisms must involve, at some stage, a transition from one metabolic strategy to another, triggered by appropriate environmental and physiological conditions. In the development of *A. suum*, the transition from aerobic to anaerobic energy metabolism is likely to occur during the third molt when larvae develop in the small intestine from the third to the fourth stage. In contrast to the adult, which lacks a functional TCA-cycle and cyanide-sensitive respiration, the earlier larval stages of this parasite rely on aerobic strategies for energy conservation resembling

Energy Metabolism, Fig. 6 Changes in the energy metabolism of *Fasciola hepatica* during its development in the final host. Contribution of the 3 pathways of glucose breakdown to ATP synthesis is shown. (After Tielens 1994)

those functional in mammalian cells. A similar adaptation is exhibited in the life cycle of *F. hepatica* (Fig. 6). While the early liver-parenchymal stages of this parasite possess a predominantly aerobic metabolism and are capable of complete substrate oxidation, these oxidative capacities decline gradually during development. In flukes between 2 and 8 weeks old, TCA cycle activity is already largely suppressed, but aerobic reactions still remain functional as characterized by the oxygen-linked formation of acetate. In this pathway, most of the chemical energy may still be conserved by mitochondrial oxidative phosphorylation, but the reducing power necessary to drive respiration is not derived from the TCA-cycle but from the formation of acetate. Compared to complete substrate oxidation, the relative efficiency of this energy-generating pathway is much lower, resulting in approximately 14 molecules of ATP per molecule of glucose catabolized to acetate and CO_2 . After arrival of the flukes in their definitive environment, the bile ducts, a further drop in oxidative capacities and relative efficiency for energy generation occurs. From this stage on, anaerobic redox-processes, resulting in the formation of acetate and propionate, remain functional throughout adult life. In the development of the liver fluke, therefore, two pronounced shifts in energy metabolism seem to occur: one being characterized by the transition from complete substrate oxidation to aerobic acetate formation, and the other by a change from aerobic to anaerobic metabolism as is observed

during the development of the late immature worms into the adult stage.

Also in schistosomes such a switch occurs from an aerobic metabolism in the free-living stages to an anaerobic one in the parasitic stages. The free-living cercariae and miracidia of *Schistosoma mansoni* possess an aerobic energy metabolism in which their endogenous glycogen reserves are degraded, mainly to CO_2 . Adult schistosomes, on the other hand, live in the bloodstream of their host and despite their small size and life in an aerobic environment, they have a fermentative metabolism and degrade glucose, mainly to lactate. When cercariae penetrate the skin of the final host and transform into schistosomula, they switch rapidly from TCA-cycle activity to lactate production via glycolysis. This metabolic switch was shown to be initiated by the sudden presence of external glucose when the free-living stages penetrate the new host, and is not linked to a decreased availability of oxygen, as in *F. hepatica*. The mere presence of external glucose results in an increased glycolytic flux, probably caused by the rapid uptake of glucose that occurs upon expression at the surface of a specific schistosomal glucose transporter protein, SGTP4. This increased glycolysis is maintained as a result of the specific kinetic properties of schistosomal hexokinase, the first enzyme in glucose catabolism. The observed rapid switch to lactate production occurs only in cercarial heads, the region of the larvae that develops into the mature parasite. The tail of

the cercaria, which only propels the organism through the water, is fully dependent on the degradation of endogenous glycogen reserves as it contains little or no SGTP4 and hexokinase, and it degenerates following the separation from the penetrating schistosomulum. In contrast to *Ascaris*, *F. hepatica* and several other helminth species, no significant changes in the energy metabolism occur during the further development of schistosomes. Lactate remains the main end product, although TCA-cycle activity and oxidative phosphorylation also contribute significantly to ATP production, even in adults.

The reason for the more pronounced oxidative capacities in developmental stages of helminths than in adults is not completely understood, but may be due to their smaller body size, which causes less oxygen diffusion problems than in adults, in conjunction with a sufficient availability of oxygen in the habitats of free-living and many parasitic larval stages. Both circumstances are likely to be essential for the establishment and function of the processes responsible for complete substrate degradation, i.e., the tricarboxylate cycle, β -oxidation route and a conventional type of phosphorylating respiratory chain. Upon increasing in body size which, for a migrating parasite, is often accompanied by a decreasing access to oxygen and changes in other environmental conditions, a marked drop in oxidative capacities often occurs in the adult, where anaerobic strategies are becoming the major ATP-generating sites. While in the latter stage these pathways cannot be reversibly replaced by aerobic processes, most developmental aerobic stages can survive anaerobically by utilizing anaerobic energy-conserving strategies which often coexist with aerobic routes. An example is *F. hepatica*, in which the ability of the adult to catabolize glucose anaerobically to acetate and propionate is present immediately after excystment and persists in all stages until the mature parasite. The interesting question of how the metabolic transitions occurring during the developmental cycle of helminths are regulated remains largely to be determined.

Energy-Metabolism-Disturbing Drugs

See Tables 1 and 2.

Structures

See Fig. 1.

Rotenoids

General Information

Rotenone is a natural product isolated from the roots of *Derris* spp. and *Lonchocarpus* spp. The derris root has long been used as a fish poison among the Malaysian natives. The insecticidal properties of derris extracts were known in China long before isolation of the active principle in 1895 by Geoffrey. Rotenone represents the most toxic and abundant member of about 13 rotenoids. Three other members also have been reported to show insecticidal activity but are less potent than rotenone: deguelin, tephrosine, toxicarol with 10 %, 2.5 %, and 0.25 % of the rotenone activity, respectively (Fig. 2). In the last 40 years rotenone has been intensively used. The world production is in the range of 10–20 t.

Molecular Interactions

Rotenone acts as an inhibitor of the electron transport system (site one) of the mitochondrial respiratory chain. It inhibits the oxidation of NADH to NAD via coenzyme Q (reducing quinone to hydroquinone), thus also blocking the oxidation by NAD of substrates such as glutamate, α -ketoglutarate, and pyruvate.

Rotenone is a nonsystemic selective insecticide with secondary acaricidal activity with contact and stomach action. It is used for the control of ► lice, ► ticks, and warble flies and against fire ants in premises as well as mosquito larvae (ponds). Today, its primary use as an ectoparasiticide is against ear ► mites and demodectic mange and in combination with other ectoparasiticides like

upon injection (LD₅₀ 0.1–4 mg/kg). Rotenone is highly toxic to pigs but shows no toxicity to bees. The compound is also used as fish toxicant in fish management. Rotenone is metabolized in the rat liver or insect by enzymatic opening and cleaving of the furan moiety or, alternatively, by oxidation of the methyl group of the isopropenyl residue.

Resistance

Resistance of ectoparasites against rotenone has not yet been described.

Iodoquinol

Synonyms

5,7-diiodo-8-hydroxyquinoline, SS578, Diodoquin, Di-Quinol, Disoquin, Floraquin, Dyodin, Dinoleine, Searlequin, Diodoxylin, Moebiquin, Rafembin,

Iloquin, Direxiode, Stanquinate, Quinadome, Yodoxin, Zoaquin, Enterosept, Embequin.

Cells and Cellular Interactions

Iodoquinol is active against ► *Entamoeba histolytica* and against facultative pathogenic *Entamoeba* spp. such as *Dientamoeba fragilis*. The activity of iodoquinol is directed against ► trophozoites (minuta forms) in the intestinal mucosa and cysts in the feces (► [DNA-Synthesis-Affecting Drugs I](#), Table 1).

Molecular Interactions

The mechanism of action is unknown. It is tempting to speculate from some structural similarities with hydroxyquinolines that iodoquinol may interfere with the energy metabolism (oxidative phosphorylation, inhibition of ATPase) in amoebes.

2-acetoloxo-N-(5-nitro-2-thiazolyl)benzamide.

Clinical Relevance

The drug was first described in 1984 as a human cestocidal drug against *Taenia saginata* and *Hymenolepis nana*. In 1994 development of nitazoxanide was re-initiated as a antiprotozoal

agent. It is active against anaerobic protozoa and bacteria (*Trichomonas vaginalis*, *Entamoeba histolytica* and *Clostridium perfringens*) (► [DNA-Synthesis-Affecting Drugs I](#), Table 1). However, nitazoxanide possesses broad-spectrum antiparasitic activities against protozoa, cestodes, and nematodes with modest to high cure rates depending on the degree of infection (light, moderate, heavy). Thus, the drug is effective against *E. histolytica*, *Giardia intestinalis*, *Isospora belli*, *Balantidium coli*,

Energy-Metabolism-Disturbing Drugs, Fig. 2 Structure of important rotenoids with insecticidal efficacy

Blastocystis hominis, *Hymenolepis nana*, *Ascaris lumbricoides*, *Ancylostoma duodenale*, *Trichuris trichiura* and *Strongyloides stercoralis*.

Moreover, nitazoxanide had resolved diarrhoea caused by *Cryptosporidium parvum* in more than 80 % of patients 7 days after beginning therapy. 67 % of patients treated with the drug did not produce *C. parvum* oocysts. There are also studies in AIDS patients conducted in Africa and Mexico with favorable results.

Molecular Interactions

Experiments in the anaerobic protozoa *T. vaginalis* and *E. histolytica* as well as in the bacteria *C. perfringens* and *Helicobacter pylori* have shown that nitazoxanide inhibits pyruvate ferredoxin oxidoreductase (PFOR), the vital enzyme of the central intermediary metabolism. By contrast to the nitroimidazoles, nitazoxanide seems to interact directly with PFOR and the products of nitazoxanide activation do not induce mutations in DNA. This different mechanism of action is important in explaining the therapeutic efficacy of this drug against metronidazole-resistant protozoa. The molecular mechanism of nitazoxanide in helminths is unclear at present.

Suramin

Synonyms

Bayer 205, 309 F, Antrypol, Germanin, Moranyl, Naganol, Naganin, Naphuride Sodium.

General Information

Suramin was explored in 1916 and originally introduced in 1922 as a trypanosomicidal drug in cattle.

Molecular Interactions

Suramin is chemically a sulfonic acid and structurally related to dyes such as trypanred, ebolblue, or trypanviolet. The six negative charges at physiological pH may be of great importance for the proposed mode of action. The action of suramin is directed against ► [trypomastigotes](#) of *Trypanosoma brucei gambiense* and *T. b. rhodesiense* in the blood dividing by ► [binary fission](#). The drug is taken up by trypanosomes via receptor-mediated ► [endocytosis](#) in presence of serum proteins 18-fold higher compared to the normal fluid endocytosis alone. Intracellular suramin concentrations (about 100 µM) are equivalent to exogenous drug concentrations. Suramin is bound to albumin and low density lipoprotein (LDL) resulting on the one hand in reduced host toxicity but on the other hand leading to an inhibition of intralysosomal proteolysis in the host cell. The complexation of suramin to albumin is also responsible for a reduced total amount of free drug in the ► [cytoplasm](#) of host cells.

The antitrypanosomal action of suramin on the molecular level is relatively unclear. There are reports on the inhibition of a variety of kinases and dehydrogenases from mammalian, bacterial, and fungal cells. In trypanosomes glycerol-3-phosphate oxidase and glycerol-3-phosphate dehydrogenase

become inhibited, resulting in a disturbed redox balance within the trypanosomal cell and a decreased ATP-synthesis rate (Fig. 3). In addition, other enzymes of *T. brucei* such as DHFR, thymidine kinase, and a number of glycolytic enzymes (hexokinase, phosphoglucose isomerase, phosphofructokinase, triosephosphate isomerase, aldolase, glyceraldehyde-3-phosphate dehydrogenase, phosphoglycerate kinase, glycerol-3-phosphate dehydrogenase, and glycerol kinase) become inhibited. The IC_{50} values of suramin on trypanosomal glycolytic enzymes (between 10 and 100 μ M) are much lower compared to the corresponding enzymes from mammalian cells. The reason for the selective toxicity may be explained by the unusually high isoelectric points (between 9 and 10) for most of the glycolytic enzymes from *T. brucei*. The basic properties of the trypanosomal glycolytic enzymes resulting in additional positive charges on their surfaces may facilitate the binding of the highly negatively charged suramin. Thus, there are likely to be potentiated inhibitory effects by electrostatic interactions between positively charged trypanosomal enzymes and negatively charged suramin, and there is no direct inhibition of trypanosomal glycolytic enzymes in ► **glycosomes**.

A further hypothesis for the suramin action on the molecular level is as follows. The nine glycolytic enzymes are synthesized on free polysomes in the parasite's cytoplasm. These enzymes are then imported into the glycosomes post-translationally without any proteolytic modification within 3–5 min and become thus protected from suramin by compartmentalization in the glycosomes. Suramin possibly binds to the glycolytic enzymes in the cytoplasm on their way to the glycosome and/or interferes with their import into the glycosomes (Fig. 3). The inhibition of glycosomal protein import is followed by a gradual decrease of enzyme concentrations in the glycosomes. The average half-life of glycolytic enzymes is about 48 h inside the glycosomes. By this action suramin induces a slowing down of energy metabolism in suramin-treated trypanosomes. The inhibition of the import of glycosomal protein is either partially or totally with disruption of ► **glycolysis** in the trypanosomes.

An additional hypothetical action of suramin is the indirect interaction with the DNA/RNA-replication resulting in retarded trypanocidal activity after 24–36 h corresponding to 4–7 divisions.

The antifilarial activity of suramin is directed against ► **macrofilariae** and to a minor degree against microfilariae of ► *Onchocerca volvulus* (► **River Blindness**). For a long time it was the only drug against adult *O. volvulus* in man, but today the use of suramin is limited. The antifilarial mechanism against *O. volvulus* is delayed (4–7 weeks after treatment). An inhibition of the cAMP-independent protein kinase I in *O. volvulus* is discussed. This protein is also the target of suramin and stibophen against ► *Ascaridia galli* in vitro. Suramin further exerts curative effects against ► *Wuchereria bancrofti* filariasis and in addition shows effectivity against all stages of *Litomosoides carinii*. There is a requirement for intravenous injection which is accompanied by severe side effects. Suramin leads to a sterilization of adult filariae. *L. carinii* in *Mastomys coucha* are killed within 6 weeks. Despite great chemical-synthetic efforts there is no possibility for improvement of better tolerability without loss of filaricidal activity. In general there is no correlation between filaricidal effects of suramin derivatives and trypanosomicidal activity.

Additional Features

Suramin has additional activities against a wide variety of pathogens. Thus it is a potential anti-AIDS drug, due to a potent inhibitory effect on the reverse transcriptase from a variety of retroviruses. In addition, an inhibitory effect on DNA polymerase activity is discussed.

Clinical Relevance

The main indication of suramin relies on the activity against early stages (bloodstream forms) of human African trypanosomes (*T. b. gambiense* and *T. b. rhodesiense*) (► **DNA-Synthesis-Affecting Drugs III**, Table 1). Suramin is usually given with five intravenous injections at a dosage of 20 mg/kg b.w. once every 5–7 days. In veterinary medicine the drug exerts efficacies against *T. b. brucei* (► **Nagana**), *T. b. evansi* (► **Surra**),

Energy-Metabolism-Disturbing Drugs, Fig. 3 Target enzymes of suramin; metabolic processes impaired by suramin are indicated by the symbol – ■; highly schematic

representation of trypanosomal cell organelles and their metabolic processes; relationships of the magnitudes of organelles are not correct

and *T. equiperdum* (► [Dourine](#)). In addition, suramin has experimental activity against *Entamoeba histolytica*, ► [Eimeria](#) spp., and avian ► [malaria](#).

Resistance

The mechanism of resistance of suramin on the molecular level is unclear. Generally the resistance to suramin is rare even after 70 years of application in trypanosomiasis field clinics. This might be an indirect support for the hypothetical action on multiple targets in trypanosomes.

Antimonials

Important Compounds

Sodium-stibogluconate, Meglumine-antimonate, Stibophen.

Synonyms

Meglumine-antimonate: N-methylglucamine antimonate, glucantime; Sodium-stibogluconate: Antimony sodium gluconate, Pentostam, Myostibin, Solustibosan, Solyusurmin, Stibanate, Stibanose, Stibatin, Stibinol; Stibophen: Sodium antimony bis(pyrocatechol-2,4-disulfonate), Sdt 91, Fuadin, Fouadin, Pyrostib, Corystibin, Trimon, Fantorin, Repodral, Neoantimosan, Sodium Antimosan.

Cells and Cellular Interactions

The antiprotozoal activity of the antimonials sodium-stibogluconate and meglumine-antimonate is directed against cutaneous, visceral, and mucocutaneous leishmaniasis (► [DNA-Synthesis-Affecting Drugs II](#), Table 1). They have no activity against cultured leishmanial ► [promastigotes](#) Stibophen shows besides the

activity against *Leishmania tropica* and *L. mexicana* also activity against ► *Schistosoma haematobium*.

Molecular Interactions

The mechanisms of antiprotozoal action of the pentavalent antimonials sodium-stibogluconate and meglumine-antimonate rely on their reduction to the corresponding trivalent antimonials by host metabolism. The activity is directed against those stages dividing by repeated binary fissions such as *L. donovani* and *L. chagasi* in spleen, liver, and skin stages, intracellular ► amastigotes of *L. tropica*, *L. major* in the skin and *L. brasiliensis* and *L. mexicana* in mucous tissues of nose and mouth. Thereby, presumably those enzymes with sulfhydryl groups become inactivated by trivalent antimonials. Thus, the inhibition of cytoplasmic pyruvate kinase and other kinases with reactive sulfhydryl groups at their active sites results in a decreased flow of glucose into the citrate cycle in *L. tropica* promastigotes in presence of trivalent antimonials, in addition, there is an accumulation of glycolytic metabolites and a disturbance of energy production within the parasites. As an alternative hypothesis a disruption of trypanothione reductase (TR) by antimonials is discussed. The real mode of antileishmanial action of the antimonials is yet unknown.

The antitrepatodal action of stibophen may be explained by the inhibition of phosphofructokinase of *Schistosoma mansoni*.

Resistance

Resistance against pentavalent antimonials is an increasing problem varying between 5 % and 70 % of patients in some endemic areas. Resistant ► *Leishmania* isolates tolerate concentrations of antimonials, which are 100-fold higher than the maximal achievable serum levels of drugs in humans.

The real mechanism of resistance against antileishmanial antimonials is still unknown. Biochemical studies indicate that there is a decreased accumulation of sodium-stibogluconate in resistant cell lines. It remains, however, unclear

whether there is a decreased uptake or an increased efflux of drug. The resistance of *Leishmania* spp. against pentavalent antimonials can be reversed in vitro and in vivo by verapamil indicating a P-glycoprotein-mediated resistance mechanism.

In addition, it was proposed that the resistance mechanism in *Leishmania* spp. against antimonials is based on gene amplifications. Such a mechanism is proposed for the resistance against different compounds such as methotrexate, arsenite, tunicamycin, DFMO, mycophenolic acid, and vinblastine.

Clopidol

Synonyms

Meticlorpindol, Clopidol, Coyden; in combinations: Lerbek (= Meticlorpindol + Methylbenzoate).

Cells and Cellular Interactions

The antiprotozoal activity of clopidol is directed against *Eimeria* spp. in chicken (► DNA-Synthesis-Affecting Drugs IV, Table 1). Clopidol leads to an inhibition of the development of sporozoites and trophozoites.

Molecular Interactions

Clopidol is a pyridone-derivative structurally related to the quinolones. Its real mode of action is unclear to date. There is no interference with mitochondrial respiration of *E. tenella*. Synergistic effects between clopidol and methylbenzoate indicate that the action of clopidol may be similar but not identical to that of quinolones. The differences are probably due to an alternative pathway of electron transport in coccidia ► mitochondria with specific sensitivity to clopidol.

Resistance

There is cross-resistance between methylbenzoate and clopidol in strains of *E. maxima*. The resistance against clopidol in a

methylbenzoquate-resistant strain appears after many passages in chicken.

The mechanism of resistance against clodolol is unclear.

Robenidine

Synonyms

Robenzidene, Cycostat, Robenz.

Cells and Cellular Interactions

The antiprotozoal activity of robenidine is directed against all five economically important *Eimeria* spp. in poultry (*E. acervulina*, *E. maxima*, *E. necatrix*, *E. tenella*, and *E. brunetti*) (► [DNA-Synthesis-Affecting Drugs IV](#), Table 1). Furthermore Robenidine exerts activity against ► *Neospora caninum* ► [tachyzoites](#) in cell cultures.

Molecular Interactions

Robenidine acts against developing first generation schizonts by possible interference with the oxidative phosphorylation and ATPase in mitochondria of *Eimeria* spp. and rat liver mitochondria. In chicken erythrocytes there is an induction of efflux of K^+ -ions observable.

Amprolium

Synonyms

1-((4-amino-2-propyl-5-pyrimidinyl)methyl)-2-picolinium chloride, Corid, Amprol, Amprovine; in combinations: Amprol Plus, Amprol Hi-E, Amprolmix, Pancoxin, Supracox.

Cells and Cellular Interactions

Amprolium has been used for the therapy of coccidiosis in poultry, zoo birds, and mammals since 1960. It has activity against *Eimeria tenella*, *E. maxima*, and *E. necatrix* (► [DNA-Synthesis-Affecting Drugs IV](#), Table 1). The action of amprolium is directed against ► [wall-forming bodies](#) II of schizonts of the first and second generation.

Molecular Interactions

Amprolium is structurally related to thiamine, but lacks the hydroxymethyl group of this vitamin. Thus, the phosphorylation to the corresponding thiamine pyrophosphate analogue is abrogated. Thiamine is an essential cofactor for pyruvate dehydrogenase activity, which is interestingly also the site of inhibition by antiprotozoal arsenicals. Amprolium competitively inhibits the transport of thiamine across the cell membranes of second generation schizonts. Amprolium possesses a high therapeutic index which may be explained by differences of thiamine transport rates between chicken epithelial cells and *Eimeria* spp.

Resistance

The mechanism of resistance against amprolium is explained by a modification of the target receptor resulting in a decreased sensitivity to inhibition. The K_i -value for amprolium is increased nearly 15-fold to 115 μ M in the resistant *E. tenella* strain.

Arsenicals

Important Compounds

Carbasone, Glycobiarsol, Melarsoprol, Thiactarsamide, Mel PH, R7/45.

Synonyms

Carbasone: N-carbamoylarsanilic acid, Amebevan, Ameban, Amibiarsone, Arsambide, Carb-O-Sep, Histocarb, Fenarsone, Leucarsone, Aminarsone, Amebarsone; Glycobiarsol: Bismuth glycolylarsanilate, Broxolin, Dysentulin, Milibis, Viasept, Wintodon; Thiactarsamide: Arsenamide, Thioarsenite, Caparsolate, Caparside, Arspenamide, Filicide, Filaramide.

Clinical Relevance

The great interest in arsenicals at the beginning of the twentieth century relied on their antibacterial activities. Thus, 4-arsanilic acid sodium ([Atoxyl](#)) and Salvarsan were the first drugs to be active against syphilis. **Carbasone** as one of the antiprotozoal arsenicals was introduced in 1931

against infections with ► *Trichomonas vaginalis* and *Entamoeba histolytica*. **Glycobiarsol** introduced in 1938 exerts activities against *T. vaginalis*, *E. histolytica*, and ► *Giardia lamblia*. **Melarsoprol** is still one of the drugs of choice for the treatment of late stage ► **sleeping sickness** caused by *Trypanosoma brucei gambiense* or *T. b. rhodesiense*. Arsanilic acid and roxarsone exhibit activity against *E. tenella* sporozoites. **Acetarsone** in combination with arecoline was used as an anticestodal drug in small animals. In addition, sodium arsanilic acid in combination with copper sulfate has antinematodal activities against ► **nematodes** in ruminants. The macrofilaricidal efficacy of arsenicals is also known for a long time. Interestingly, all arsenicals obtain almost exclusively adulticidal effects which is clinically proven in man. **Thiacetarsamide** potassium is a drug routinely used against ► *Dirofilaria immitis* in the dog (► **Inhibitory-Neurotransmission-Affecting Drugs**, Table 1). Another arsenical is **melarsomine** used as adulticide against *D. immitis* in dogs. The main disadvantage of the arsenicals are their severe side effects, such as the arsenical encephalopathy. In the meantime new and less toxic organic arsenicals such as **Mel PH** and **R7/45** have been developed. In general, there are no marked reductions of microfilariaemia levels until day 7 p.i. and the adulticidal efficacy of drugs varies with the parasite species. Thus, thiacetarsamide is much more active against *Brugia* spp. than other arsenicals; ► *Acanthocheilonema viteae* is more resistant to Mel PH and **R7/45** than *Litomosoides carinii* and *B. malayi*. Arsenicals exert better activity against female *L. carinii* and *B. malayi* than against males whereas both worm sexes of *A. viteae* are equally sensitive to arsenicals.

Molecular Interactions

The mechanism of action of antiprotozoal arsenicals is presumably due to an inhibition of glycolytic enzymes and/or protein kinases with SH-groups. Also trypanothione reductase may be a target of some arsenical compounds such as melarsoprol (► **DNA-Synthesis-Affecting Drugs III**, Fig. 1).

The antifilarial arsenicals lead to an in vitro and in vivo inhibition of ► **glutathione** reductase as shown in *L. carinii* adults. Thereby, the parasitic

enzyme is more susceptible to inhibition than the corresponding mammalian enzyme.

Clorsulon

Synonyms

L-631,529, MK-401, Curatrem, in combinations: Ivomec Plus.

Clinical Relevance

Clorsulon belongs to the fasciolicidal drugs (Table 1) with good activity against ► **liver flukes** (► *Fasciola hepatica*) from the age of 4 weeks. It has low toxicity and is excreted rapidly. Clorsulon is suitable for the use in meat-producing animals. Now clorsulon is used in combination with ivermectin (Ivomec F).

Molecular Interactions

It is the only one of the most commonly used fasciolicides whose action is directed against glycolysis on the level of 3-phosphoglycerate kinase and phosphoglyceromutase. There is no great disruption of glycolysis in vivo by clorsulon. At a concentration of 500 µg/ml for 1 h the glucose utilization is decreased by 60 %, formation of acetate and propionate is inhibited by 54 % and 85 %, respectively, and ATP levels are reduced by 67 %. The motility of the ► **flukes** is gradually suppressed ending in a flaccid paralysis which may be explained by the slow depletion of energy reserves and cessation of feeding. Until now there are no reports about clorsulon resistance.

Isothiocyanates

Important Compounds

Bitoscanate, Nitroscanate.

Synonyms

Bitoscanate: Jonit, Bitovermol, Sicur; Nitroscanate: Lopatol, Cantrodifene, Canverm.

Clinical Relevance

Nitroscanate was introduced in 1973. Its anticestodal activity is directed against ► *Taenia*

Energy-Metabolism-Disturbing Drugs,

Fig. 4 Action of anthelmintics by uncoupling of oxidative phosphorylation

bunamidine
disophenol, nitroxylin,
dichlorophene, hexachlorophene, bithionol(sulfoxide)

bitoscanate, nitroscanate

spp., ► *Dipylidium caninum* and *Echinococcus granulosus* in dogs (► **Membrane-Function-Disturbing Drugs**, Table 1). Furthermore, nitroscanate is used in dogs against ► **hookworms** and ► *Toxocara* spp. Bitoscanate exerts activities against ► *Ancylostoma* and *Necator*.

Molecular Interactions

There are no data about the mode of action of nitroscanate in ► **cestodes**. There is one report showing that the ► **ATP synthesis** in the trematode *Fasciola hepatica* is inhibited (Fig. 4).

Halogenated Monophenols

Synonyms

Disophenol: AncyloI, DNP, Iodophene, Syngamix; Nitroxylin: Fasciolid, Dovenix, Trodax.

Clinical Relevance

Disophenol and nitroxylin are two members of monophenols with antitrepatodal activity against *Fasciola hepatica* (Table 1). Moreover, disophenol exerts antinematodal activity against ► *Haemonchus contortus*.

Halogenated Bisphenols

Important Compounds

Bithionol, bithionol sulfoxide, Meniclopholan.

Synonyms

Bithionol: Actamer, Bitin, Loroithidol; Bithionol sulfoxide: Bitin-S, Disto-5; Meniclopholan: Niclofolan, Bayer 9015, Me 3625, Bilevon-M, Dertil, Distolon.

Clinical Relevance

Bithionol and bithionol sulfoxide (so-called thiobisphenols) were the first members of the class of halogenated bisphenols discovered in the 1930s. Dichlorophene was introduced in 1946 and hexachlorophene in the late 1950s. The anticestodal activity of these drugs is directed against *Taenia saginata*, ► *T. solium*, *Diphyllbothrium latum*. They have some effects against *Hymenolepis nana*. These compounds are now replaced by more active drugs.

Hexachlorophene has some additional antitrepatodal activity against mature *Fasciola hepatica*, ► *Dicrocoelium dendriticum*, adult paramphistomes (Table 1). Dichlorophene shows activity against ► *Fasciolopsis buski* (Table 2)

and bithionol against ► *Paragonimus* spp. (Table 2). Furthermore, bithionol is active against immature and adult paramphistomes (Table 1). However, it is toxic at the effective antitreumatodal dose rate. Another member of the bisphenols, menichlopholan (= niclofolan) has fasciolocidal activity and high effectivity against immature paramphistomes in sheep (Table 1), but not against immature and adult flukes in cattle. Niclofolan exhibits additional activity against ► *Metagonimus* spp. (Table 2).

Characteristics

The structure-activity relationships for the fasciolocidal activity of bisphenols are similar to that for monophenols. The safety index of monophenols and bisphenols is generally rather low between 1 and 4. Disophenol and nitroxynil obtain as electron-withdrawing substituents halogen, nitro, or cyano groups, which are necessary in at least the ortho- and/or para-positions of the phenol for the fasciolocidal activity. Nitroxynil, niclofolan, bithionol, and hexachlorophene have structural similarity to 2,4-dinitrophenol, a known uncoupler of oxidative phosphorylation in mammalian systems (Fig. 4).

Molecular Interactions

The mode of action studies with mono- and bisphenols have been carried out in isolated cestodal or mammalian mitochondria but not in liver flukes. Nevertheless, it is proposed that the action of monophenols and bisphenols relies on the decrease of ATP synthesis.

Salicylanilides

Important Compounds

Niclosamide, Oxyclozanide, Cliofoxanide, Rafoxanide, Brotianide, Bromoxanide, Closantel, Resorantel.

Synonyms

Bromoxanide: none; Brotianide: 3,4'-Dibromo-5-chlorothiosalicylanilide acetate, Bay 4059, Dirian; Cliofoxanide: 2-Acetoxy-4'-chloro-3,5-diiodobenzanilide, Tremerad; Closantel: Flukiver,

Seponver; Niclosamide: Mansonil-P, Lintex-M, Mansonil-M, Yomesan, Bayluscid, Cestocid, Devermin, Fenasal, Radeverm, Sagimid, Tredemine, Vermitin; Oxyclozanide: 3,3',5,5',6-Pentachloro-2'-hydroxysalicylanilide, Zanol, Diplin, Metiljin; Rafoxanide: 3'-Chloro-4'-(p-chlorophenoxy)-3,5-diiodosalicylanilide, MK-990, Bovanide, Duofas, Flukanide, Ranide, Ursovermid; Resorantel: Resorcytan, Terenol.

Clinical Relevance

The first salicylanilide niclosamide was discovered in 1958 and introduced in the early 1960s as anticestodal drug. The fasciolocidal activity of diaphene was discovered in 1963.

Niclosamide exerts anticestodal activity (► **Membrane-Function-Disturbing Drugs**, Table 1). It was the drug of choice in cestodiasis before the discovery of praziquantel. It has high curative efficacy against *Taenia saginata*, *T. solium*, *Diphyllobothrium latum*, *Hymenolepis nana*, ► *Mesocestoides* spp., and *Dipylidium* spp., but only low activity against *Echinococcus granulosus*. Its absorption from the intestinal tract is poor (only 2–25 % absorption in the first 4 days), and it is not accumulated in any organ. More than 70 % of the drug is excreted via feces and the excretion is completed within 1–2 days. Resorantel, another salicylanilide, exhibits anticestodal activity against ► *Moniezia expansa* in ruminants.

In general, the antitreumatodal activities are the main actions of salicylanilides. Niclosamide exerts activity against immature paramphistomes. It is regarded as the most effective and safe compound for the control of an outbreak of paramphistomiasis (Table 1). However, it has no effectivity against adult paramphistomes in ruminants. In general, drugs with high efficacy against the adult flukes are not active enough for elimination of pasture contamination. Furthermore Niclosamide has activities against intestinal flukes (*Fasciolopsis*, *Metagonimus*, *Heterophyes*, *Echinostoma*, *Gastrodiscoides*, *Watsonius*, *Nanophyetes*) (Table 2), but it is not active against *Fasciola hepatica*.

Diaphene is a mixture of 3,4,5'-tribromosalicylanilide (**tribromsalane**), the main component

and fasciolicidal compound, and 4',5-dibromosalicylanilide used as a germicide. Tribromsalane was a new lead structure in the 1960s for a variety of salicylanilides such as **oxyclozanide**, **clioxanide**, **rafozanide**, **brotianide**, **bromoxanide**, and **closantel**. Salicylanilides show an increased potency against adult and particularly also against immature flukes. They possess a greater therapeutic index between 4 and 6 compared to the halogenated phenols with a therapeutic index between 1 and 4. With salicylanilides mass treatment of sheep and cattle is possible for the first time, because they have good activity against 4–6 week old immature flukes.

Resorantel, a 4'-bromo- γ -resorcydanilide-derivative, is a specific and the most effective drug against immature and adult paramphistomes in sheep, goats, and cattle with slightly erratic, but good efficacy. In addition it has some activity against *Gastrodiscoides* (Table 2).

Oxyclozanide is probably the most suitable drug for the control of an outbreak of acute intestinal paramphistomes in calves, especially in concurrent *Fasciola*-infections.

Besides their anticestodal and antitreumatodal activity, salicylanilides are also active against some nematodes. Thus, rafoxanide and closantel are active against the blood-ingesting nematode *Haemonchus contortus* (Table 1).

Molecular Interactions

The mechanism of the anticestodal action of niclosamide is the uncoupling of oxidative phosphorylation from electron transport in cestodes (Fig. 4). Thereby, protons are translocated through the inner mitochondrial membrane. There is a measurable decrease of ATP synthesis in $\blacktriangleright$ *Ascaris* muscle mitochondria. The selective toxicity of niclosamide is explained by its poor absorption from the host intestine resulting in a protection of host cells against the uncoupling properties of this drug.

The fasciolicidal salicylanilides possess highly lipophilic groups like iodine, chlorophenoxy, tert-butyl-substituents which are responsible for prolonged plasma half-lives between 2 and 4 days. Rafoxanide and bromoxanide have even longer half-lives of 5–6 days. Moreover, there is

slow excretion resulting in persistent drug residues. Therefore, several weeks of withdrawal periods before slaughter are necessary and most of the phenol-type fasciolicides are not used for treatment of milk-producing ruminants.

For rafoxanide, oxyclozanide, and closantel there is more direct evidence for an uncoupling action within the fluke (Fig. 4). An increased end-product formation by 32 % and decreased ATP-synthesis by 29 % by rafoxanide can be detected. Furthermore, there is an increased glucose uptake, decreased glycogen content, enhanced end-product formation (succinate), increased mitochondrial ATPase activity, reduced ATP levels by closantel. A probable correlation between death of the flukes and reduced ATP levels is discussed. A deformation of mitochondria in many fluke tissues is observable. The $\blacktriangleright$ **Golgi apparatus** in the tegumental and gastrodermal cells is reduced in size and contains vacuolated cisternae. The basal infolds of the $\blacktriangleright$ **tegument** are swollen and ion pumps associated with the tegumental membranes are inhibited. There is as a result a general induction of rapid spastic paralysis of the adult flukes by the action of the presumptive uncoupler-type fasciolicides such as rafoxanide, oxyclozanide, nitroxylin.

Resistance

A selection of resistant strains of *Fasciola hepatica* in Australia has occurred by prolonged use of rafoxanide and closantel. There is cross-resistance between salicylanilides and the halogenated phenol nitroxylin. The resistance is manifest against immature but rarely against adult flukes. There is no side resistance in rafoxanide- and closantel-resistant liver flukes to oxyclozanide. It is assumed that selection for resistance in the case of rafoxanide and closantel is favored by possible differences in the mode of action and pharmacokinetic properties between oxyclozanide on the one hand and rafoxanide/closantel on the other hand. Thus, quick peak concentrations in the blood and quick elimination are seen with oxyclozanide in contrast to the strong binding to plasma proteins with rafoxanide and closantel resulting in long-lasting persistence in the blood at therapeutic concentrations for more than 90 days.

Cyanine Dyes

Important Compounds

Pyrvinium, Dithiazanine iodide.

Synonyms

Dithiazanine iodide: Abminthic, Anelmid, Anguifugan, Delvex, Dejo, Deselmine, Dilombrin, Dizan, Nectocyd, Partel, Telmicid, Telmid; Pyrvinium pamoate: Pyrvinium embonate, Viprynum embonate, Alnoxin, Molevac, Neo-Oxypaat, Pamovin, Poquil, Povan, Povanyl, Pyrcon, Altolat, Tolapin, Tru, Vanquil, Vanquin, Vermitiber.

Clinical Relevance

Pyrvinium exerts antinematodal activity against *Enterobius*, *Trichuris vulpis*, dithiazanine iodide against *T. vulpis*. In addition, dithiazanine iodide has experimentally antifilarial activity against *Litomosoides carinii*.

Molecular Interactions

The antinematodal action against *T. vulpis*, a nematode residing in a more anaerobic environment, is probably the inhibition of glucose uptake by dithiazanine and also by pyrvinium. Responsible for the antifilarial action of dithiazanine is presumably the irreversible inhibition of oxygen uptake of adult *L. carinii*, an oxygen requiring nematode.

Entamoeba gingivalis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *enteron* = intestine; *amoibe* = change;
Latin: *gingiva* = gingiva, gums.

Geographic Distribution/Epidemiology

Worldwide, common; especially frequent in cases of lacking or reduced mouth hygiene.

Morphology/Life Cycle

This amoeba, which reaches a size of 5–30 µm, is found in dental plaques of more than 50 % of the world population. The trophozoites show a strict separation of the hyaline ectoplasm from the granular endoplasm, which contains the cell organelles and the food vacuoles. The nucleus looks similar to that of ► *Entamoeba histolytica*, since the nucleoplasm is condensed at the periphery of the nucleus and the nucleolus is also situated centrally. Feeding is done by phagocytosis of bacterial and host cellular remnants especially in cases of inflammations. Cysts had never been observed and the membrane bound trophozoites do not survive the passage of the intestine. Thus transmission must run on oral contact during kissing or due to common use of spoons, teeth brushes, etc.

Symptoms of Disease

Normally none; however, it is not definitively proven that there is no participation in the formation of abscesses or in gum bleeding.

Diagnosis

Microscopical investigation of portions of teeth plaque diluted in 0.85 % NaCl show motile amoebae with their typical nucleus (Fig. 1).

Infection

The trophozoites are transmitted from one to the other person by mouth to mouth contact or by common use of teeth brushes, spoons, etc.

Entamoeba gingivalis, Fig. 1 Diagrammatic representation of the typical *Entamoeba gingivalis*

Prophylaxis

Care for constant mouth hygiene and avoid common use of teeth brushes.

Incubation Period

Unknown.

Prepatency

Unknown.

Patency

Months or even years as consequence of lacking mouth hygiene.

Treatment

Special treatment in immunocompetent persons is not needed, since the trophozoites are killed by products used during oral hygiene. However, in case of immunocompromised persons, where several infected gingival pockets, gingival ulcers or

other periodontal diseases occur, treatment with paromomycin is recommended.

Entamoeba histolytica

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *entos* = inner, *amoibos* = changing shape, *histos* = tissue, and *lysis* = dissolution of tissues.

Geographic Distribution/Epidemiology

These amoebae are found in warm countries all over the world, but are also often imported by travelers and refugees into temperate climatic zones (Fig. 1). More than 500 million humans are constantly infected. Death tolls per year are calculated 75,000–100,000. About 10 % of the world population is constantly endangered.

Morphology/Life Cycle

This amoeba may occur in three different stages inside the intestine of humans (Figs. 2, 3, 4, and 5).

- (a) Minuta stage (10–20 µm)
- (b) Magna stage (20–40 µm)
- (c) Cyst stage (10–15 µm)

Minuta and magna stages are characterized by a hyaline ectoplasm, a single hernia sack-like protruding pseudopodium at the anterior pole of the cell and as seen in colored specimens by their typical nucleus and by condensation of the chromatin at the inner side of the inner nuclear membrane (Figs. 2, 3, and 4). The centrally situated nucleolus is smaller than that of *E. gingivalis*. The minuta stage lives in the intestinal fluid and divides by binary fission. Feeding occurs by phagocytosis of particles from the intestinal fluid. When being transported in the region of the colon (where water retraction occurs), the minuta stages excrete a cyst wall and this stage now appears spherical (Figs. 2, 4c). The nucleus inside the young cyst divides and each of the progeny divides again once, so that cysts excreted with the feces each contain four nuclei all showing the typical central nucleolus (Figs. 2, 4c). Even completely asymptomatic, persons may excrete 30–40 millions of these cysts per day in endemic regions. Since normal light microscopic investigations do not show differences between the newly described nonpathogenic species *Entamoeba dispar* and *E. histolytica*, it must be suggested that these reports of the excretion of millions of cysts are mainly based on infections with *E. dispar* and/or on apparently existing

nonpathogenic strains of *E. histolytica*. It is estimated that *E. dispar* covers about 90 % of the excreted cysts. Recently it was shown that *E. nuttalli* cysts found in macaques are genetically different from *E. histolytica*, but appear identical.

Under certain conditions not well understood even today, the minuta stages may switch into magna stages (Fig. 5), which are able by excretion of substances (amoebapora) to attach at the cells of the intestinal wall, to destroy them, to find a way to enter blood vessels, and thus to reach finally the liver, where they form so-called liver abscesses (ameboma), which are filled by a brownish fluid consisting of bacteria, remnants of host cells, and rather few amoebae. These abscesses can easily be seen in computer-tomographic images, reaching diameters of 12–15 cm and may become life-threatening (Fig. 7).

Symptoms of Disease

The disease due to amoebic stages which lyse – according to their species name *histolytica* – liver tissues is called in literature entamoebiasis, amoebic dysentery, or red dysentery. There are distinguished two different phases:

Entamoeba histolytica, Fig. 1 Distribution map of amoebic dysentery (WHO)

Entamoeba histolytica, Fig. 2 Life cycle of *Entamoeba histolytica*. 1 Cysts with 4 nuclei (i.e., metacysts) are ingested orally with contaminated food or drinking water (a-c). 2-4 After excysting in the small intestine, both the cytoplasm and nuclei divide to form 8 small amoebulae (i.e., metacystic trophozoites). 5, 6 Mature trophozoites (i.e., minuta forms) reproduce by constant binary fissions. 7 Uninucleate cyst (i.e., precyst) contains chromatoid bodies and (often) a large glycogen vacuole. 8 Cysts with 2 nuclei and chromatoid bodies. 9 Cysts with 4 nuclei (metacysts) are set free with the feces and become

infectious when ingested by man. 10-11 Some of the minuta forms may grow to magna forms, which enter the intestinal wall and, via the bloodstream, other organs such as the liver, lung, and brain (11a-c), where they lead to abscesses (i.e., ameboma). Living amoebae are only found at the periphery of these ameboma. (AB abscess; CH chromatoid body; CW cyst wall; E erythrocyte; P single, pale pseudopodium; N nucleus with central nucleolus (karyosome); NV food vacuole; V glycogen vacuole of young cysts (for further species, see Amoebae/Table 1)

Entamoeba histolytica,

Fig. 5 Two magna forms seen by help of Nomarski contrast

(a) **Intestinal amoebiasis:** Shortly after the infection, the patients complain light gastrointestinal symptoms such as feeling of abdominal pressure, wandering pain along the intestine, symptoms of vomiting, but never fever. The sudden onset of fever would be a sign of an infection with bacteria (bacterial dysentery). At the beginning of an intestinal amoebiasis, the stool is formed or slightly pasty/mushy and contains whitish slime components. Ongoing with the infection, the number of defecations increases up to 5–10 per day (there are even more in cases of bacterial dysenterias!). In case of amoebic dysentery, feces are only rarely fully watery, but contain in most cases bloody traces and larger amounts of slime, appearing like raspberry jelly (Fig. 6), while bacterial dysenterias appear yellowish-whitish purulently. During ongoing intestinal entamoebiasis, the general fitness of the patients becomes reduced. Ulcerations of the colon wall grow in number and start to confluence, while the so-called bottleneck and buttonhole ulcers are formed. Their borders are evaginated and their depth often reaches into the muscularis propria. These invaginations become quickly filled by huge amounts of bacteria. Depending on the size, localization, and number of these ulcers, the patients suffer from colic pain, decreasing

fitness, and intermittent high fever. Since blood vessels are often destroyed inside the ulcers, the dysenteric stools contain increasing amounts of blood (Fig. 6). In case arteries become lysed, life-threatening bleedings may occur, which require surgical actions. All these symptoms resemble strongly the symptoms of a colitis ulcerosa; however, magna stages of *Entamoeba histolytica* do not occur there.

As complication of the intestinal entamoebiasis, a so-called intestinal ameboma structure may occur, which is a locally limited tumor, which is of the benign type but is also able to block (at least in parts) the discharge of the feces. Further complications such as perforation of the intestine and peritonitis may occur as a consequence. In several untreated cases, the intestinal symptoms may disappear; however, there is no guarantee that all infectious stages had disappeared.

(b) **Extraintestinal amoebiasis:** This disease does not necessarily take a dramatic course. Very often slight abdominal pain and increased numbers of defecations remain for long the only symptoms. Also the examination of the blood does not show much peculiarities. This slow progress of the symptoms, however, does not exclude the hidden formation of abscesses in the liver, but also in the lung or even (rarely!) in the brain.

Entamoeba histolytica,
Fig. 6 Portion of bloody
stool

Entamoeba histolytica,
Fig. 7 Section through a
liver with several abscesses
(ameboma)

This phase of the early formation of an abscess may start only after months or even after years and is characterized by weakness, fever around 38–39 °C (usually without ague), and feeling of increasing local pain due to formation of cavities in tissues. With respect to the correct medical term, *E. histolytica* does not form true “abscesses,” since there is no limiting membrane or a wall around the hollow that occurs in the organs

due to lysis of the tissues. Most *Entamoeba* abscesses are situated inside the right liver portion and initiate due to their quick and intense increase spontaneous pressure pain in the region of the upper right belly. In case the abscess is situated close to the diaphragm, it leads to sting-like pain during breathing. The patient lays rightward bended, breathes only slightly, and refuses touching. Occasionally an infiltration is formed by remnants of an

inflammation along the right thorax wall. These symptoms are connected with an extremely high leukosis in the peripheral blood (reaching often values of more than 20,000/ μ l). The quickly increasing erythrocyte sedimentation rate (ESR) is a leading symptom for the existence of an acute liver abscess (ameboma) due to *E. histolytica* (Fig. 7). Investigations using ultrasonic waves or by help of computer tomography will confirm the presence of such abscesses. As soon as treatment is done, the symptoms of the disease are quickly reduced. Already on the following day of treatment, pain, fever, liver swelling, and inflammation symptoms decrease considerably. If this relief does not occur, the abscess has probably another origin and might be based on a tumor, on infections with bacteria, or on an infection with ► *Echinococcus* cysts. Depending on the size of the abscess, chirurgical intervention (e.g., sucking off the fluid of the abscess) may be needed but has to be done at all caution in order to avoid penetration of amoebae into the peritoneum. The surgeon has to decide whether intervention is needed or whether application of medicaments is recommended.

Diagnosis

In the case of an **intestinal entamoebiasis**, cysts and trophozoites (minuta forms) can be microscopically diagnosed in material obtained from stools or by help of endoscopy. Cyst stages of *E. histolytica* can be demonstrated when using methods of fecal enrichment (M.I.F.C., S.A.F.C.; Fig. 4c). Modern PCR techniques may significantly differentiate between pathogenic and non-pathogenic species. However, motile magna forms would show their single pseudopodium only in fresh and body warm material. But the size (20–40 μ m) and the engorged erythrocytes in those amoebae are characteristic and basis of a sure diagnosis. If an immediate investigation is

not possible, the obtained material must be adequately preserved, e.g., in PVA, M.I.F.C., or S.A.F.C. solutions. In colored preparations (Heidenhain, trichrome, or Lawless), which were prepared from fresh or PVA-fixed material, the trophozoites of *Entamoeba histolytica* can be significantly differentiated from apathogenic intestinal amoebae by help of the structure of their nuclei. Sections of the intestinal wall also would show magna forms (Fig. 5). Stool from patients with perforated intestinal wall shows bloody contents (Fig. 6).

Extraintestinal amoebiasis is proven by the help of serodiagnostic techniques (IFT, ELISA) or by PCR, but to prove is not even easy at the beginning, and thus tests have to be repeated several times. However, in cases where the abscess has reached a certain size, computer tomography or sonograms are the techniques of choice (Fig. 7).

Infection

Infection occurs by oral uptake of the typical 4 nuclei containing cysts (Figs. 2, 4c) within contaminated drinking water or food. **Attention:** Flies may transmit mechanically such cysts, since they may glue at their feet or are included in their feces.

Prophylaxis

Avoid eating unwashed or non-peeled fruits or non-washed salads. Drinking water has to be cooked in endemic regions. Flies have to be kept off from kitchen or stored food.

Incubation Period

Two to 21 days; formation of abscesses in the liver and other organs may start about 1–3 months after an intestinal infection.

Prepatent Period

Two to seven days.

Patency

Eventually years.

Treatment

Medicaments of choice are nitroimidazoles, since they act as well against stages in the intestine as against amoebic stages disseminated in different organs. For example, metronidazole (3×500 – 700 mg daily for 5–10 days for adults or 30 mg/kg body weight daily for 5–10 days) has very good curative effects. However, after metronidazole treatment, cyst excretion may persist, although there are no more symptoms of disease. These cases can be cured by application of diloxanide (3×500 mg daily oral for 10 days) or paromomycin (3×500 mg daily oral for 8–10 days). In cases of bleeding due to perforations surgical intervention is needed. **Attention:** Do not use metronidazole or paromomycin during pregnancy.

Entamoeba nuttalli

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species infects nonhuman primates and may induce like *E. histolytica* of humans and *E. invadens* fatal outcome of infections.

Entamoeba Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In the intestine of humans, several species of the genus *Entamoeba* occur (Fig. 1). Most of them are nonpathogenic like *E. dispar*, which was separated from *E. histolytica* only by molecular biological methods, since it looks identical to *E. histolytica*, but does not penetrate the intestinal wall (Fig. 1).

Entamoeba Species, Fig. 1 Diagrammatic representation of common amoebas inside the human intestine (depicted in size relation). For species determination (among other criteria), shape and position of the nucleolus inside the nucleus is used. The motion direction is

indicated by arrows. BS pseudopodium (only one is formed), CK chromidial body (reserve material), E human erythrocyte, N nucleus, NT nucleus during division, NV food vacuole, PS pseudopodium, RV reserve material (reacts on iodine), ZW cyst wall

Entamoeba suis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This pathogenic species of pigs was considered to be synonymous with *E. polecki* as their specimens are morphologically indistinguishable from each other. However, molecular studies examining the small subunit ribosomal RNA (SSUrRNA) gene have shown a clear phylogenetic distance.

Main Clinical Symptoms in Humans

▶ Abdominal pain, bloody-slimy ▶ diarrhoea, liver dysfunction in case of liver ▶ abscess.

Incubation Period

2–21 days.

Prepatent Period

2–7 days.

Patent Period

Years.

Diagnosis

Microscopic determination of cysts in faecal samples.

Prophylaxis

Avoid uncooked food/water in endemic regions.

Therapy

Treatment see ► [Antidiarrhoeal and Antitrichomoniasis Drugs](#).

Enterobiasis

Pathology

Enterobiasis is a human infection with the ubiquitous pinworm, ► *Enterobius vermicularis*. This small nematode has a simple life cycle in the intestinal lumen (► [Pathology](#), Fig. 22A). The adult female deposits eggs in the anal canal and on the perianal skin, causing irritation leading to itching. The adults are sometimes found in the lumen and even the mucosa of the vermiform appendix, but their role in causing appendicitis is in doubt. Ectopic worms may be found in the vagina, uterus, migrating up the fallopian tubes into the peritoneum, and occasionally elsewhere, where they tend to die and become surrounded by small granulomas containing eosinophils (► [Pathology](#), Fig. 27B–D). It has been speculated that eggs of *Enterobius* spp. transmit *Dientamoeba fragilis*, which may cause diarrhea, sometimes with blood and mucus.

Enterobiasis,
Fig. 1 Targets and
approaches for the control
of enterobiasis

Targets for Intervention

Infections with the nematode ► *E. vermicularis* tend to be transmitted directly from man to man (anus-hand-hand-mouth), and self-reinfection is frequent since the worm eggs are immediately infective. However, some infections are also indirectly transmitted through contaminated material. Figure 1 shows potential targets and approaches of intervention.

The main targets will be infective reservoir and transmission from man to man. The approaches to control consist of detection and treatment of infections, and improving personal ► [hygiene](#) and food hygiene. Blanket presumptive treatment campaigns without prior diagnosis have been successfully conducted, especially in populations of children with high infection rates. The best results were obtained with repeated treatment at an interval of 2–4 weeks.

Main Clinical Symptoms

► [Pruritus](#) analis, ► [diarrhoea](#), disturbances of sleep.

Incubation Period

1–4 weeks.

Enterobiasis, Fig. 2 Eggs of *Enterobius vermicularis*

Prepatent Period

E

Enterobius vermicularis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *enteron* = intestine; *bios* = life. Latin: *vermicularis* = wormlike. Greek: *oxys* = quick; *ura* = tail.

Geographic Distributions/Epidemiology

Worldwide, there are at least 1–5 billion humans infected – this so-called pinworm is besides ► [Ascaris lumbricoides](#) one of the most common worms infecting humans.

Morphology/Life Cycle

This worm belongs to the worm group of ► [nematodes](#) and got its trivial name pinworm, since the whitish, about 8–13 mm long, females possess a long, pin-like terminal end (Figs. 1, 2, and 3). The males are smaller, reach mostly a length of only 3–5 mm. Their hind end is curved and contains a single copulatory ► [spicule](#) (Fig. 1). They die just after copulation and thus can be seen in/on human stools. The adult worms live in the colon and the females leave at night the colon, pass the anus,

Enterobius buckleyi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is an enterobiid species (pinworm) of the Sumatran orangutan, which together with the

Enterobius vermicularis,**Fig. 1** Life cycle of*Enterobius vermicularis*.

1 a/b Whitish adult males (**1 a**: $2\text{--}5 \times 0.6\text{ mm}$) and females (**1 b**: $8\text{--}13\text{ mm}$ in length) live in the colon and rectum of man (especially children). **2/3** After copulation females migrate (at night) through the anus onto the perianal region, lay numerous (10,000) eggs, and die. **4** Eggs embryonate within 6 h, forming the infectious first larval stage. **5** These eggs may be swallowed, or hatched larvae may enter the intestine directly via the anus or erroneously via the vagina of women. **6** Inside the intestine, the life cycle is completed within 4–6 weeks, leading to mature adults inside the colon (ES esophagus, L larva, TE testis, UT uterus, V vulva)

and depone their typical eggs (Fig. 4) at the skin of the host's perianal skin and thus are practically never found in the stool. Already 5 h later, the larvae are formed inside the eggs and may infect the same host or become attached at toilet seats and thus may be transmitted to other hosts.

Symptoms of Disease (Enterobiasis, Pinworm Disease)

Mostly children are infected and they "import" the worms into the family so that very often all family

members are infected due to so-called ping-pong infections. As most common symptom is noted that children sleep inquietly due to the itching effects (pruritus analis) induced by wandering females in the perianal region. Only in cases of very heavy infections with large numbers of adult worm symptoms like abdominal pain, diarrheas occur. However, in rare cases also infections of the liver are found, and especially in cases of female patients, often worms had entered the urogenital system or even the peritoneal cavity leading to organ-specific disturbances. Recently many cases of allergy have been reported in infected children, too.

Enterobius vermicularis,

Fig. 2 Microscopic photo of a female of *E. vermicularis* showing the typical pin-like posterior end

E

Enterobius vermicularis, Fig. 3 Light micrograph of the anterior end of a female worm showing a bulbous enlargement. Note that this worm is surrounded by excreted eggs

Diagnosis

Microscopical determination of the typical eggs (Fig. 4), which measure about $50\text{--}60 \times 20\text{--}30 \mu\text{m}$, must be obtained by help of a glueing transparent plastic strip which is pressed in the

morning onto the skin around the anus. Occasionally also moving or dead females can be seen there.

Infection

The infection occurs by oral uptake of eggs after anal-mouth contacts (self-infection) or by contact to contaminated sites at toilets (e.g., seats, door, latches). Furthermore shaking of sleeping suits or blankets may lead to an inhaling of worm eggs.

Prophylaxis

Handwashing after each visit of a toilet. In the case of a persisting enterobiasis, cleaning of the perianal skin and daily change of the underwear.

Incubation Period

One to four weeks.

Prepatent Period

Four to ten weeks.

Patency

Eventually years due to permanently repeated self-infections. A single female has a lifespan of about 3–4 months.

Enterobius vermicularis, Fig. 4 Light micrograph of numerous eggs of *E. vermicularis* glueing on a plastic stripe

Therapy

Single doses of mebendazole (100 mg) or albendazole (200–400 mg) (children below 15 years: 15 mg/kg bodyweight) and other anthelmintics like pyrinium or pyrantel are very efficacious to cure a pinworm infection. Since normally repeated self-infections occur and the products in general do not kill all larval stages, it is recommended to repeat the treatment 2–3 times at intervals of 2–3 weeks and (!) to treat simultaneously all members of a family living in the same rooms. In high-graded infections also 5–6 repeated treatment series had been necessary.

Enterocytozoon

Classification

Genus of ► [Microsporidia](#).

Enterocytozoon bienewsi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *enteron* = intestine; *kytos* = cell; *zoon* = animal; Bieneus = family of the first patient (♀) detected.

Geographic Distribution/Epidemiology

Worldwide; the first description occurred in France on material from a female Haitian patient. *E. bienewsi* represents about 40 % of all human infections due to microsporidia. About 10 % of the AIDS patients are infected in general with microsporidia in addition to other opportunistic agents of disease. *E. bienewsi* mainly infects AIDS patients.

Morphology/Life Cycle

Characteristic and name-giving for the microsporidia is the tiny sized spore, which is the infectious stage. Their life cycle derives in the same phases as diagrammatically described in Fig. 1 of *Encephalitozoon cuniculi*. The ovoid spores are ovoid, measure $1.5 \times 0.5 \mu\text{m}$. They possess a five times wound polar tube and their endospore is rather thin. In case such a spore is orally ingested within contaminated food or drinking water, inside the intestine the hollow tube is expelled and injected like a syringe into an epithelial cell of the intestine. The cytoplasm (endoplasm) of the spore creeps through the tube, enters the cytoplasm of the host cell (whereby a parasitophorous vacuole is formed), and starts a repeated asexual reproduction (merogony) via 2-nucleated cells ($3\text{--}4 \mu\text{m}$ in diameter). Later on one of these cells starts sporogony by producing asexually 2-nucleated plasmodia, which develop finally after fusion of both nuclei into eight spores. In immunocompetent patients, they are excreted with the feces, since the host cell is disrupted at the end of the spore formation. In case of AIDS patients, however, apparently the freshly formed spores rupture and their sporoplasm enters the immediate neighbor host cells and thus a massive **autoinfection** occurs.

Symptoms of Disease

Intermittent diarrheas (without blood contaminations) occur 3–10 times per day for 4–5 months. This leads to weakness, loss of weight, nausea, abdominal pain, and fever. This extreme severity does not occur in immunocompetent patients. However, spores of *E. bieneusi* had also been found in stressed tourists after returning home from their voyages.

Diagnosis

Microscopical demonstration of spores in feces or in intestinal biopsies. Coloration can be done by use of trichome or fluorescent products. In special laboratories PCR tests are also available.

Infection

Oral uptake of spores with contaminated food or drinking water. Also persistent **autoinfection** is possible, after ingestion of only a small amount of spores.

Prophylaxis

Avoiding contact to contaminated food, drinking water, or fecally contaminated sites in rural regions.

Incubation Period

One week.

Prepatent Period

One week.

Patency

More than 5–6 months, depending on the status of immunocompetence of the patient.

Treatment

Not very well known. Albendazole had shown in-vitro a significant efficacy, however, in-vivo only 3 % of the treated persons were cured (when given $2 \times 400 \text{ mg/day}$). Furthermore metronidazole ($1\text{--}2.5 \text{ mg per day}$) and cotrimoxazole had been successfully tested. **Important:** Replacement of water is absolutely needed.

Entomological Inoculation Rate

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes the number of bites by ► [mosquitoes](#) infected by ► [Plasmodium](#)

(or by other agents of diseases) in a defined period (usually per year or per period of mosquito activity). Thereby the infection risk is calculated for local people and foreigners entering an endemic region. For example, about 700 bites of infected mosquitoes per year would lead to a 90 % chance to get malaria.

Entomological Inoculation Rate Formula

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This formula is noted as **EIR = maY** and describes the amount of infectious bites per person per year or day.

a is the amount of blood meals of a given vector on humans, **m** is the density of vectors in a given territory, and **Y** is the amount of mosquitoes with parasites in their salivary glands.

Entomology

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek: *entomos* = with notches; *logos* = knowledge.

The science of insect life.

Entomopathogenic Fungus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This is a member of the group of fungi that can act as a parasite of insects or other arthropods, killing them or disabling them. Their activity is recently tested in order to use them as a “biological bio-cide” in insect or tick eradication.

Entopolypoides

Genus of blood parasites that is now considered to belong to the genus. ► *Babesia*. Two human cases had been described due to *E. macaci*.

Envelope

Locke proposed the name envelope for all such extracellular structures which have dimensions similar to those of plasma membranes and which are formed at membrane surfaces. Such envelopes (e.g., 3 in ► *Trichinella spiralis*) occur in a variety of organisms, from bacteria to vertebrates. More information is needed about their biochemical and functional properties, since they allow many different transport processes and are apparently resistant towards hosts’ digestive enzymes as well as cellular attacks.

Environmental Conditions

Claude Combes
Centre de Biologie et d’Écologie Tropicale et Méditerranéenne, Université de Perpignan, Perpignan, France

It is well known that parasites are more detrimental to their hosts when environmental conditions

make the latter more vulnerable, principally because resources are limited and, as a consequence, immune defences weakened. In humans for instance, periods of famine are often aggravated by epidemics.

This happens also in the wild. De Lope et al. write: "It is inherent in the definition of parasitism that parasites are costly to their hosts. Costs can be measured in absolute terms, but may vary in relative magnitude as a consequence of variation in access by hosts to essential resources. If parasites are costly to their hosts in terms of fitness, they should be so to a larger extent under stressful environmental conditions."

De Lope et al. have tested this prediction by comparing the impact of the ► [ectoparasite](#) ► *Oeciacus hirundinis* on its bird host, the house martin *Delichon urbica*. (The parasite feeds on the blood of nestlings and can cause their death.) All nests under study were fumigated in order to kill the parasites, then: (a) First third of nests were left without parasites, (b) 10 ► [bugs](#) per nest were added in the second third, and (c) 100 bugs per nest were added to the last third. The authors then studied various parameters of bird reproduction, especially hatching success and fledging success (In the area -southern Spain- where the study was carried out, usually two broods are reared each year.) They showed that (Fig. 1):

- In the nests without (or nearly without) parasites, hatching and fledging successes are close to 100 % in both clutches;
- In the nests with few bugs, there is little decrease in hatching and fledging successes in the first clutch, but in the second clutch the success goes down to ~50 %;
- In the nests with a high parasite load, the first clutch is still little affected, but the second clutch experiences a dramatic decrease of reproductive success.

Fledging and fledging success of second broods thus decreased considerably with increasing parasite intensity. In other words, parasites were more costly to house martins in the second clutch. The explanation is that the second clutch is reared when food (*D. urbica* is a strictly

Environmental Conditions, Fig. 1 Hatching (H) and fledging (F) successes of house martin in first (1st) and second (2nd) clutches (original, data from de Lope et al.)

insectivorous passerine) is less abundant: the negative effects of parasites on their hosts increase as external conditions become worse. One may conclude that, when food is readily available, the

negative effects of parasites are compensated on the part of the hosts to such an extent that decrease of host fitness is virtually absent or at least difficult to detect. In contrast, the impact of parasites on host fitness increases dramatically when environmental conditions are poor.

Environmental Parasitology

Bernd Sures and Milen Nachev
Aquatic Ecology, University of Duisburg-Essen,
Essen, Germany

General Information

Environmental parasitology (EP) addresses the question which ecologically relevant information can be obtained by identifying or analyzing parasites in the environment. In the common understanding, two different branches of EP exist. Whilst the more ecologically based approach is interested in parasites as indicators for environmental health, the more medically oriented understanding of EP specifically concerns the occurrence and diagnosis of human parasites in the environment.

Medically Based EP

Infective stages of helminths and protozoan parasites are very resistant to environmental conditions. Their occurrence in food and water used for human consumption or recreational purposes represents one important way of parasite transmission to humans. Although disinfection methods used in conventional waste water and drinking water treatment are often very effective in removing or killing transmission stages, sophisticated water treatment plants are not established everywhere in the world. Provided that the fecal-oral cycle is not completely separated, infective stages may be present in drinking water and thus lead to human infections. Moreover, as a consequence of insufficient hygienic conditions, infective stages

may also occur in water used in agriculture or for recreational purposes. Therefore, detection of infective stages in the environment is an important element in medically based EP to identify possible sites of food or water contamination and usually represents the basal step in risk analysis and disease prevention. Many protozoic parasites, such as *Cryptosporidium* sp., *Giardia lamblia*, and *Entamoeba histolytica*, are important pathogens causing human mass infections and numerous waterborne disease outbreaks. Furthermore, helminths, most noticeably *Schistosoma* spp. causing schistosomiasis or bilharziasis, are relevant agents of waterborne diseases that require ongoing attention. Accordingly, the medically based EP combines approaches of ecology and medicine with technological aspects concerning water treatment with the ultimate goal to reduce the parasite load in water used for all kinds of human activities.

Ecologically Based EP

Due to the ecological role parasites play in ecosystems, their relevance as indicators of environmental health has gained increased attention in recent years. Accordingly, ecologically based EP consists of an intimate interaction between parasitology and disciplines of classical and applied ecology, and covers biotic aspects like the functional and structural integrity of ecosystems, food web dynamics, and trophic interactions as well as abiotic information concerning environmental chemistry and pollution. In recent years, many papers have focused on parasites as potential indicators of human impacts on the environment (Vidal-Martínez et al. 2010). Because of their functional importance in animal communities (e.g., their position in foodwebs) and their substantial contribution to ecosystem biodiversity (40 % of all species are assumed to possess a parasitic life style during some phases of their ontogeny), parasites are useful bioindicators particularly for monitoring anthropogenic pollution. Under certain circumstances, pollution can negatively affect parasites, for example, if pollutants decrease the lifespan of infected hosts and thereby

impair parasite reproduction, if parasites are more sensitive to a particular pollutant than their intermediate or final hosts, or if pollution drives the necessary hosts extinct. However, pollution can also increase parasite prevalence and intensity if host defense mechanisms are negatively affected, which in turn increases host susceptibility, or by leading to environmental conditions that increase population densities of suitable intermediate or final hosts. Effects of pollution may vary between species of parasites as well as between their developmental stages. Free-living larval stages that are occurring in water or soil (e.g., digenean miracidia and cercariae, nematode larval stages, cestode coracidia, etc.) are often much more sensitive to pollutants than adults which live inside their definitive hosts. Accordingly, similar to free-living organisms, parasites are affected by environmental conditions and respond to them either in a general or a specific way. Fluctuations in parasite population dynamics (e.g., outbreaks of parasitic infections) are still not well understood, but it appears that changes of environmental conditions such as pollution or other anthropogenic impacts play a crucial role. In terms of applicability of parasites as early warning signs or indicators of pollution they can be – similar to free-living organisms – divided into effect bioindicators and accumulation bioindicators (Sures 2004). Additionally, parasites can interfere with established bioindication procedures, owing to their effects on the physiology and behavior of the respective intermediate and final hosts. This could lead both to false-negative and false-positive indications of pollution if biomarker analyses are performed in environmental monitoring programs.

Parasites as Effect Indicators

In ecotoxicology, effect indicators deliver information about the ecosystem health and integrity through changes in their physiology, which in turn may manifest in population size and community diversity. Existing literature on effect indication with parasites mainly focuses on the level of individual organisms, populations, and

communities. Concerning individual parasitic organisms, effect indication might be possible using the direct toxicity of substances on free-living parasitic stages, especially miracidia and cercariae of trematodes (Pietroock and Marcogliese 2003). For this approach, a known number of larval stages are treated with chemicals and the subsequent longevity, viability, and infectivity of these stages are analyzed. Compared to conventional automatic effect indication procedures using algae, daphnids, or fish, cercarial test systems appear to be less promising. Nevertheless, these approaches can be used to evaluate effects of pollution on transmission of parasites and the subsequent composition of parasite assemblages.

Environmental factors can influence parasite populations directly or indirectly. If the intermediate or final host is negatively affected, population and community effects may manifest at first on the level of free-living organisms and subsequently on the parasite level. Ectoparasites of fish, which have direct contact with the ambient environment, were found to react quickly and sensitively to environmental stressors such as eutrophication and chemical pollution which leads to reduced species richness and unequal distribution of abundances in hosts (Dušek et al. 1998). Similar effects, however, were also observed for endoparasites with free-living stages (see above).

Although changes of parasite populations and communities have been analyzed frequently with respect to environmental pollution, it is difficult to generalize these findings. Until now only a few parasite–pollution combinations show predictable changes despite the considerable effort that has been put into linking levels of environmental pollution with parasitism (Vidal-Martínez et al. 2010). It is, however, clear that environmental pollution does affect parasite populations and communities, both directly and through effects on intermediate, paratenic, and final hosts.

Analyses of parasite community structures might still be advantageous compared with established effect indication procedures using free-living animals as it integrates effects of environmental parameters over different trophic levels. For example, the ratio between species richness of heteroxenous and monoxenous (S_H/S_M) parasites

can be used as a measure of pollution impact. In unpolluted marine habitats, the S_H/S_M ratios on/in fish were higher in comparison with fish which were sampled from polluted habitats, as monoxenous parasites show a higher susceptibility to pollution than heteroxenous species (Perez-del Olmo et al. 2007).

Parasites as Accumulation Indicators

A large number of studies have demonstrated the usefulness of parasites as accumulation indicators (Sures 2003; Vidal-Martínez et al. 2010). Accumulation indicators are organisms which are able to bioconcentrate certain substances inside their body to concentrations exceeding those in host tissues and the ambient environment. Thus, they can provide valuable information about the chemical state of their habitats and deliver insights into the variety of toxic substances occurring therein. The use of accumulation indicators is advantageous compared to chemical analyses as the indicator organism shows the degree of biological availability of pollutants, i.e., the fact that a specific substance occurs in the environment gives no information about a possible uptake by organisms. Different groups of parasites have been already investigated with respect to their capacity of accumulating pollutants. Among them, endoparasites such as acanthocephalans and cestodes turned out to be highly effective in metal uptake and accumulation (Sures 2003). Laboratory as well as field studies have shown that concentrations of various toxic metals in acanthocephalans surpass ambient concentrations many times and even exceed those detected in already established free-living accumulation indicators. Accordingly, it might be advantageous to use the most sensitive accumulation indicators for assessing the presence and availability of anthropogenic pollution in pristine areas such as the Antarctic or for detection of substances which usually occur in lowest concentrations.

In addition to the possible use of parasites as accumulation indicators and their enormous accumulation capacity combined with high resistance to toxic effects lead to a significant reduction of

pollutant concentrations in the tissues of their hosts. This kind of detoxification process might be beneficial for the host organism in comparison to uninfected conspecifics, as infected hosts suffer less from toxic effects of chemicals.

Interactions of Pollutants and Parasites on Hosts

The number of studies investigating effects of pollutants and concurrently occurring parasites has been increasing steadily in recent years (Sures 2008; Marcogliese and Pietrock 2011). Apart from the fact that parasites can eventually be advantageous with respect to a reduction of pollutant accumulation in host tissues, they also may have profound negative effects on the host physiology. Parasites often act as stressors that negatively affect the physiological homeostasis of their hosts. If these stressors occur under polluted environmental conditions, their effects on host physiology may be synergistic, neutral, or antagonistic to pollution effects. Accordingly, parasites may in one way or the other affect the host's pollutant metabolism. Organisms that are confronted with environmental pollutants detoxify chemicals in different ways depending on the pollutant type. Toxic substances are transformed into nontoxic substances, excreted, or deposited in places where they are not toxic. It emerges from recent field and experimental studies that the presence of parasites in hosts exposed to pollutants leads to severe alterations of all detoxification measures with usually more harmful effects than either of the stressors alone. In terms of life expectancy, a combination of these stressors therefore results in higher mortality rates. Accordingly, animals in polluted environments might be more at risk than is currently perceived in risk assessments based on current toxicity testing programs which do not consider parasites as additional stressors. Given the ubiquitous occurrence of parasites, their possible negative effects have to be considered on the regulatory level when defining environmental safety limits of pollutants.

Apart from this synergistic combination of adverse effects for the respective individual

organism, the simultaneous occurrence of parasites and pollutants is also relevant for environmental monitoring studies. The pervasive presence of pollutants in the environment fosters the development of evaluation tools for the assessment of pollutant impacts on aquatic organisms in addition to chemical analyses. This has led to the idea of using biological markers (biomarkers) which indicate the presence of contaminants and unravel their effects on organisms. Biomarkers are usually biological parameters based on changes in behavior, physiology, biochemistry, genomic structure and expression, and are used as easily accessible early warning signs of disturbances at the individual level. They can be divided into contaminant specific markers (e.g., metallothioneins as markers for metals) and less specific markers being part of a general stress response (e.g., hormones, heat shock proteins). The most commonly used biomarkers, however, are not only sensitive to anthropogenic pollutants but might also be induced by a variety of natural stressors, especially parasites. Although biomarkers are applied under complex field conditions, knowledge about their possible modulation by naturally occurring parasites is still limited. Manipulation of biomarker response by infected hosts easily leads to misinterpretation of pollution scenarios, if parasitism is not being taken into account, which is a clear plea for intensification of research in this area of EP.

Enzyme-Linked Immunosorbent Assay (ELISA)

This is a type of sandwich-test for the diagnosis (e.g., of parasites) using antigen or antibodies that were marked with enzymes. In case of **antigen-ELISA** a specific antibody (directed against the antigen) becomes attached at a plate. Then the test substance (with the antigen) is filled onto the plate thus giving rise to antibody-antigen-complexes. As next step a second antigen specific antibody, which is marked with an enzyme, is added. If then the test substrate is added, the antigen can become qualitatively and quantitatively determined.

Eomenacanthus

Genus of ► [Acanthocephala](#).

Eosinophilia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: eos = reddish colour; philein = loving.

This term describes the results of an infection, e.g., with different nematodes (e.g., ► [Ascaris](#), ► [Toxocara](#), ► [Ancylostoma](#), Necator). This overcrowding production of white blood cells and their occurrence in the blood occurs when larvae 3 of the above noted nematodes pass the lungs on their way to their final habitat (intestine).

Eosinophilic Meningoencephalitis

Disease in humans, e.g., due to infections with ► [Angiostrongylus cantonensis](#) (L 3 enter the brain and die there). Such infections were reported from more than 30 countries in South East Asia, Africa, Australia and America.

Eperythrozoon

Genus of rickettsiales (e.g., *E. suis* in pigs), transmitted mechanically by blood suckers.

EPG

Eggs per gram of feces. Method to measure the intensity of an infection using the techniques of the McMaster chambers or of the Kato-Katz smears.

Epicuticle

The outermost layer of the ► [cuticle](#) in ► [nematodes](#). It is between 6 and 60 nm thick and consists mainly of 2 dark lamellae separated by a lighter

interspace (► [Nematodes](#), Figs. 7B and 8E, ► [Nematodes](#)/► [Integument](#)).

Epidemia

From Greek: *epi* = over, above; *demos* = people. Occurrence of diseases in different groups of hosts.

Epidemic Spotted Typhus

Disease of humans due to infection with the spherical, 0.3–0.5 µm-sized *Rickettsia prowazekii* stages transmitted by the feces of ► [lice](#) (*Pediculus humanus corporis*) via inhalation or skin scratching. After an ► [incubation period](#) of 10–14 days high fever occurs leading to death in 20 % of (untreated) cases.

Therapy

Tetracyclines.

Epidemic Zone

► [Geographic Zones of Occurrence of Diseases](#); infections occur at intervals.

Epidemiology

Epidemiology (expression in medicine) or ► [epizootiology](#) (expression in veterinary medicine) is a science dealing with occurrence, distribution, prevention, and control of disease, injury, and other health-related events (e.g., influence of climatic conditions) in a defined animal or human population.

Epidermal Growth Factor (EGF)

Apical addition of this factor may block the activity of *Giardia*-trophozoites to disrupt the tight junction-zone of their host cells.

Epieimeria

► *Eimeria* species, ► *Coccidia*.

Epimastigotes

Developmental stage of ► *Trypanosomatidae* mostly found in the intestine of the vectors. The single flagellum is anchored in the mid of the cell body (beyond the nucleus), ► *flagella*.

Episome

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes DNA within a cell, which is not integrated in a chromosome, but is normally found in a closed circle.

Episthmium Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trematodes of the family Echinostomatidae. Life cycle see *Echinostoma*. The adults occur besides in their typical hosts (e.g., dogs = *E. caninum*;

egrets; *E. chauhani* intermedium) also in humans, if they ingest infected raw intermediate hosts (fish).

Chemical Class

Macrocyclic lactone (16-membered macrocyclic lactone, avermectins).

Mode of Action

Glutamate-gated chloride channel modulator. Nematocidal Drugs, ► [Ectoparasiticides: Antagonists and Modulators of Chloride Channels](#).

Equine Protozoal Encephalomyelitis (EPM)

Disease of horses due to cerebral infection with the coccidian parasite *Neurospora*. Another often fatal viral disease is called equine encephalomyelitis (EEM).

Equine Protozoal Myeloencephalitis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

► EPM.

This disease is due to cerebral infections with the horse *Sarcocystis* species *S. neurona*. See ► [Sarcocystis](#) species of horses and other equids.

Ergasilus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The genus *Ergasilus* belongs to the crustacean family Copepoda. The specimens reach a length of up to 3 mm and their second antennae are transformed to strong claws, which help the females become attached to the surface of fish, while males are free-living in water (where copulation occurs). A swimming larva (a so-called Nauplius) hatches from fertilized eggs. After four so-called copepodit larvae, the adult stage is reached (Fig. 1).

Ergasilus, Fig. 1 Diagrammatic representation of an adult female with two egg bags (ES)

Eubothrium crassum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This tapeworm belongs to the family Amphicotyliidae and reaches as an adult worm a length of up to 6 cm inside the intestine of a salmonid fish. The plerocercoid larvae are found in salmonids and also in other fish species.

Eucestoda

Classification

Subclass of ► [Cestodes](#).

General Information

The adult members of the Eucestoda are extremely dorso-ventrally flattened, appear mostly white-opaque, and inhabit the alimentary system of vertebrates (except for *Archigetes* spp., which may also reach sexual maturity in freshwater oligochaetes; Table 1). Most ► [tapeworms](#) are polyzoic animals (Fig. 1, p. 498) characterized by the repeated occurrence of sets of reproductive organs (exceptions are members of the orders Caryophyllidea (► [Caryophyllaeus laticeps](#), Fig. 1) and Spathebothriidea). With the exception of the members of the order Dioecocestidae (parasites of the grebe and ibis), the tapeworms are protandric hermaphrodites (monoecious animals) which cover a size range from 1 mm up to 25 m. Apart from the caryophyllideans, which are considered as sexually mature larvae (► [Progenesis](#), ► [Neoteny](#)) of pseudophyllideans, members of the Eucestoda show a characteristic body differentiation into ► [scolex](#), neck, and ► [strobila](#) consisting of a few to up to 4000 proglottids (Figs. 1, 2, and 3, pp. 498–500).

The scolex is very small (mostly less than 1 mm) and endowed with specific holdfast systems such as ► [rostrum](#), acetabula, suckers, bothria, grooves, and hooks (Fig. 4, p. 501; ► [Cestodes](#), Fig. 1). The small neck region is the continuously differentiating zone that produces immature proglottids; the cytological processes are only poorly understood. The strobila, representing the main bulk of the body, consists of a more or less long chain of proglottids. The latter contain, in a species-specific pattern, 1 or

Eucestoda, Fig. 1 (a–c) Diagrammatic representation of the organization of an eucestodean tapeworm (e.g., *Hymenolepis* sp.) showing the repeated reproductive organs and the common systems (nerves, excretory channels). Note the folded surface leading to the aspect of separate proglottids. Parenchymal muscles are left out. EC, cross-running excretory canal (connecting the ventral longitudinal vessels); EG, egg

(containing the oncosphere); EL, longitudinally running excretory canals (2 on each side); NL, nerves running longitudinally, PR proglottis, OV ovary, RS receptaculum seminis, SC scolex, ST subtegumental cells and muscle layer (circular, longitudinal), TE testis, TG tegument, UE uterus filled with eggs, VD vas deferens, VG vagina, VI vitellarium.

Eucestoda, Fig. 2 (a–d) Diagrammatic representation of the reproductive organs within proglottids of different genera of tapeworms. Note the different size and number of testes, the occurrence of an uterus opening, and the position of the genital porus. In (a) (*Diphylobothrium* spp.) only 1 of the 2 vitellaria and half of the branched male system is drawn. *Dipylidium caninum* (d) has 2 sets

of reproductive organs per proglottis. *EC* cross-running excretory channel, *EL* longitudinal excretory channel, *GP* genital porus, *NL* nerve running longitudinally, *OT* ootype, *OU* opening of the uterus, *OV* ovary, *TE* testis, *TG* tegument (details not drawn), *UT* uterus, *VD* vas deferens, *VG* vagina, *VI* vitellarium.

2 sets of sexual organs which, however, do not mature at the same time. Just behind the neck proglottids are immature, then further posteriad there are proglottids with mature male organs, then those with mature female organs, and finally those whose uterus contains fertilized eggs; the latter proglottids are thus described as gravid. Copulation occurs before egg formation; a

given proglottid can copulate with itself, with others in the same strobila, or with those in other worms. When a gravid proglottid reaches the end of a strobila, it detaches (► [Apolyosis](#)) and passes out intact with the feces (e.g., ► [Taenia](#) spp.) or partly disintegrates before reaching the anus (*Vampirolepis*/*Rodentolepis* = *Hymenolepis*). In cases where

Eucestoda, Fig. 3 (a–d) *Hymenolepis nana*: organization of the strobila. (a, c) Light micrographs of semithin sections, (b, d) scanning electron micrographs. A Longitudinal section of young proglottids (PG). Note the formation of infoldings at the distal end of proglottids ($\times 250$). B, C Typical aspects of mature craspedote proglottids in longitudinal section (c) and surface view (b). Note the overlapping region (OL) and the absence of a definite border between the

proglottids in C. (B $\times 80$, C $\times 100$). D Pore at the end of the terminal proglottid, through which eggs (EG) may pass ($\times 80$). E Excretory channel (connecting the longitudinal vessels), EG egg, IF infolding of the tegument, LS layer of subtegumental cells, OL overlapping part of the preceding proglottid, PG proglottid, PM parenchymal muscles (here running longitudinally), PO pore, TG tegument, UE uterus filled with eggs.

the uterus has an opening, the proglottids release the eggs and become detached when exhausted (Pseudoapolytic, ► **Anapolytic**; e.g., ► *Diphyllobothrium*). Besides the sexual organs (repeated in each proglottid), some systems (such as excretory canals, nerve fibers, body wall with ► **tegument**, longitudinal muscles) are common to the whole worm and run from the scolex to the posterior end (Fig. 1).

In general, ontogenesis of members of the Eucestoda proceeds as a ► **metamorphosis** using

different larval stages in alternating hosts (► **Cestodes**, Fig. 2, Table 1). The first and most common larva is the 6-hooked ► **oncosphaera**, which is infectious to intermediate hosts and develops into other larval stages (► **Cestodes**, Fig. 2). In some species some of these later larval stages give rise to an asexually produced generation (e.g., ► *Echinococcus*, *Taenia multiceps*, ► *Mesocostoides* sp.), thus initiating a ► **metagenesis**, which is characterized by alternating sexually and asexually reproducing generations.

Eucestoda, Fig. 4 Scanning electron micrograph of typical platyhelminthic holdfast organs: *Taenia* spp. scolex with rostellar hooks (H) and suckers (SU) ($\times 150$). N neck region, R rostellum.

Important Species

See Table 1.

Eucoccidium

Genus of the ► [Protococcidia](#); ► [Grellia](#).

Eucoleus

Synonyms

Capillaria contorta, the females reach a length of 2 cm, the males 12 mm; they live in the esophagus of goose, duck, chicken.

Eucoleus aerophilus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek, *eu* = true; *koleos* = sheath. Latin: *aerophilus* = air loving. Synonym for *Capillaria aerophila*. See ► [Capillaria Species](#) of animals.

Eucoleus boehmi (syn. *Capillaria boehmi*)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This species is the etiological agent of the nasal eucoleosis (capillariosis) of canids. The adults measure 12–64 mm in length and 0.008–0.12 mm in width. Its morphology is similar to *Eucoleus aerophilus* (syn. *Capillaria aerophila*).

Eufilaria

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of filarial worms of birds; the adults live within the subcutaneous tissues, while their short (~120 µm long) unsheathed microfilariae occur within the blood, from where they are ingested by ► **ceratopogonids** (= midges).

Euglenozoa

Phylum of protozoans (e.g., it contains the ► **Kinetoplastida**, with specimens of the genus ► *Trypanosoma*.
► **Classification**.

Eukaryonts

Old name for ► **Eukaryota**. See also ► **Nuclear Division**.

Eukaryota

Eukaryotes may consist of a single cell or they may be multicellular organisms – termed ► **Metazoa** – made up of differentiated (specialized) cells. They may be unicellular in all their developmental stages (► **Protists**), or unicellularity may be limited to certain

developmental stages, such as the sexual stages (Gametes) of plants and animals. Even highly differentiated ► **Metazoa** retain vestiges of their unicellular origin, as shown by their development from unicellular “eggs,” some of which may develop even if they are not fertilized. They also have the ability to reconstruct their whole bodies from a single cell, as do easily the sponges, but also the fertilized ► **oocytes** of vertebrates. Eukaryotic cells consist of a membrane-bound ► **cytoplasm** (containing 1 or more nuclei and various organelles

Eukaryota, Table 1 Differences between prokaryotes and eukaryotes

Attributes	Prokaryotes	Eukaryotes
Cell nucleus	–	+
DNA-amount	Low (up to 1.4×10^{-2} pg/cell)	High ($1.6 \times 10^{-2} - 96$ pg/cell) (in haploidity)
Organization	Circular	Linear (chromosomes) plus circular elements
Recombination	Conjugation	Meiosis and syngamy
Introns	–	+
Cell division	+	+

+ Present, – Not present

that are also often membrane-bound, their compartments and membranes acting as sites) where reaction processes can occur. The most significant differences between the components of eukaryotic and prokaryotic cells are listed in Table 1.

Eulimdana

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of filarial worms of birds, which live as adults and microfilariae in the connective tissues of the skin, from where they are ingested by their vectors (mallophages = biting lice). The microfilariae are sheathed and reach a length of about 120 µm. See ► [Filarial](#) worms of animals.

Eumitosis

► [Nuclear Division](#) of the metazoans during which the nuclear membrane disappears.

Euparyphium melis

Species of the trematode order Echinostomatida.

EuPathDB

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Database for eukaryotic pathogens providing access to genomics and functional genomics information (<http://eupathdb.org/eupathdb>).

Euphemism

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *au* = true; *phemism* = mode of thinking.
This term is used when health authorities minimize true infection dangers in local epidemics.

Euploidy

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

These cells possess the normal number of chromosomes, i.e., two copies of each chromosome in a diploid organism.

Eurartesim[®]

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This antimalarial product contains the compounds artemisinin and piperaquine.

Eurytrema

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of the trematode family Dicrocoeliidae. *E. pancreaticum* (8–16 × 5–8 mm, Fig. 1) is

found in the pancreas of ruminants, pigs, camels, and monkeys in Asia and South America. *Eurytrema* species related to birds are occasionally found in humans.

Eurytrema, Fig. 1 Adult from pancreas duct of a pig

Eurytrema pancreaticum, Fig. 1 Light micrograph of a colored specimen of *cpcp* of a goat (Prof. Dr. Schuster, Dubai)

Eurytrema pancreaticum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *eurys* = broad; *trema* = hole. Latin: *pancreaticus* = belonging to the pancreas.

This species, which parasitizes in the pancreas of cattle and other farmed ruminants (like *E. coelomaticum*) but also in pigs, camels, and monkeys in Asia and South America, reaches a length of about $8\text{--}16 \times 5\text{--}8$ mm (Fig. 1). Its life cycle runs similar to that of ► *Dicrocoelium dendriticum*. It uses land snails of the genera *Bradybaena* and *Ganesella* as first intermediate hosts and grasshoppers as second ones.

Further Reading

Eurytrema procyonis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *eurys* = broad; *trema* = hole;
prokyon = “predog” = raccoon.

This species, which lives inside the ductules of the pancreas of raccoons and rarely in cats and dogs, in the USA and Canada, reaches a length of only 1.7–2.5 × 0.7–1.3 mm and thus is very tiny compared to related species. The life cycle is similar to that of ► *Dicrocoelium dendriticum*. Land snails are used as first final host (*Mesodas* species) and several arthropods as second ones. The life cycle is not completely established but seems similar to that of ► *Dicrocoelium dendriticum*.

Euryxenie

Greek: *euris* = wide/large; *xenos* = foreign; species with a large spectrum of possible hosts.

Euschongastia indica

Species of the mite family Trombiculidae, the larvae of which live as parasites.

Eustrongylides Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This genus includes worldwide occurring nematode species, which share their life cycle between water birds and fish. The species *E. tubifex*, *E. ignotus*, and *E. excisus* are found as larvae in several species of fish and oligochaetes and parasitize in the intestine of water birds. However,

since several species also occur in fish eaten by humans (e.g., eels in China), human infections have been described.

Eutely

Absence or strict reduction of all divisions, e.g., ► [cell multiplication](#) in ► [nematodes](#) after last hatching is very restricted (if not entirely absent) -except within the reproductive system, midgut, epidermis, and somatic muscles.

Eutrichomastix lacertae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trichomonadida parasite in the intestine of lizards.

Eutrombicula alfreddugesi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This mite species is a relative of the European “chigger” ► [Neotrombicula autumnalis](#) and

occurs in biotopes ranging from the southern states of the USA to the Amazonas regions. Symptoms of the sucking activity of mites are haemorrhagies at the biting site, erythema, and progredient intensive pruritus. **Treatment:** application of antihistamine and cortisone.

Evasion

From Latin: *evadere*. Active slip out of parasites (e.g., ► [Oxyuris](#)). ► [Immune Responses](#).

Evasion Mechanisms

Mechanisms of parasites to avoid the attacks of the immune system ► [Amoebiasis](#), ► [Cysticercosis](#), Giardiasis, Man, ► [Sleeping Sickness](#); ► [immune Responses](#).

Exacerbation

From Latin: *acerbare*. Increase of the intensity of symptoms of disease.

Exanthema

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Latin term for skin inflammations due to several reasons; e.g., exanthema is induced by ► [Sarcoptes](#) mites, by ► [lice](#) and by ► [Leishmania](#) species.

Excavata

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Supergroup of unicellular eukaryotes including
 several human parasites such as trypanosomes.

Further Reading

Hampl V et al (2009) Phylogenomic analyses support the
 monophyly of Excavata and resolve relationships
 among eukaryotic super groups. Proc Natl Acad Sci
 U S A 106:3858–3864

Excoriation

Clinical and pathological symptoms (loss of
 surface layers) of infections with skin (Latin:
corium) parasites (Skin Diseases, Animals,
 ► [Demodicosis](#), Man).

Excretion

The process of eliminating waste materials
 (► [Exocytosis](#)).

Excretory Gland

Some ► [Nematodes](#) possess paired glands to
 drain their body cavity, others have the so-called
 H-cell-system running as channels inside the lat-
 eral chords. Crustaceans developed similar excre-
 tory systems at the bases of antennae and/or their
 coxae (= first segment of leg).

Excyzoite

Stage that hatches from the 4-nucleated
 cyst of *Giardia*, as soon as the cyst has reached
 the small intestine a few hours after oral
 ingestion.

Exflagellation

Formation of microgametes of ► [Plasmodium](#)
 species in the gut of female anopheline
 mosquitoes.

Exocytosis

The process of ► [excretion](#) similar to ► [endocy-
 tosis](#) but in reverse. It may occur anywhere on the
 surface or, as in ciliates, at a specialized place
 called the ► [cell anus](#) or ► [cytopyge](#).

Exopalgiger

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

The genus name is used as synonym for *Ixodes*
trianguliceps.

Exophagic

► [Mosquitoes](#) that bite mainly outdoors (e.g.,
Anopheles albimanus in Central America).

Exospore

Outer layer of spore wall in microsporidians.

Exportins (XPOs)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes conserved export receptors, which help to export several proteins and different species of RNA (being formed inside the nucleus) through the nucleus pores into the surrounding cytoplasm. Apparently XPO1, XPO5, and XPOT are immediately involved in the in-and-out transport processes of noncoding RNA. All three genes are present in fungi, plants, and animals of the deuterostome group, while one gene is lacking in the protostomes. However, it was shown that it is also present in the protostome worm *Schistosoma mansoni*.

Further Reading

Abreu FCP et al (2013) Characterization of export receptor exportins (XPOs) in the parasite *Schistosoma mansoni*. Parasitol Res 112:4151–4159

Exposition

Period during which hosts are exposed to possible transmission of agents of disease or time that have blood suckers for engorging parasitic stages.

Expression Associated Genes (ESAG)

At the plasma membrane of trypanosomes the transferring receptor is encoded by ► [VSG](#) gene

expression site associated genes (ESAG) no. 6 and 7 (with several alleles). However, only one form is expressed at a time.

Expulsion

Name

Latin: *expulsare* = eject.

Some drugs paralyse intestinal worms, which then are expelled and may start creeping in the feces: Living worms are also ejected during vomitory process.

Extended Phenotype

The notion of extended phenotype is due to Richard Dawkins, who defined it as “all the effects of a gene upon the world.” In parasitology and more practically, it is the expression of a parasite’s genotype into the phenotype of its host.

Many species of parasites manipulate the morphology and/or the behaviour of their hosts with the aim of facilitating their transmission to the next host in the life cycle. This is specially true when parasites have a life cycle involving an intermediate host. Dawkins writes: “Parasites that have a life-cycle involving an intermediate host, from which they have to move to a definitive host, often manipulate the behaviour of the intermediate host to make it more likely to be eaten by the definitive host.”

One of the first experimental demonstrations of an extended phenotype was achieved by Bethel and Holmes who showed that uninfected freshwater amphipods *Gammarus lacustris* tend to avoid light and remain close to the bottom of the lakes, whereas individuals infected by the acanthocephalan *Polymorphus paradoxus* stay close to the surface and cling to surface debris. This behaviour makes them more vulnerable to surface-dabbling ducks, and thus facilitates parasite transmission.

Dawkins regards the altered behaviour of the amphipods as an adaptation on the part of the parasite: “We may, therefore, talk of worm genes having phenotypic expression in shrimp bodies, in just the same sense as we are accustomed to talking of human genes having phenotypic expression in human bodies.” Since the publication of a chapter by Bethel and Holmes in 1973, a great number of host phenotype manipulations by parasites have been reported. Poulin has drawn attention to the fact that energy spent on host manipulation is not available for other functions, which means that manipulation has a cost and must be optimized by selection as any adaptive trait. Maybe one of the most extraordinary examples of extended phenotype concerns immune avoidance by Strepsiptera, a group of insects which parasitize other insects. When penetrating a new host, the larva of the strepsipteran manipulates host epidermal tissue so that it may wrap within it; the larva is thus dissimulated to host immune defense; it is the manipulated host epidermis which constitutes a barrier to the host hemocytes.

The expression of parasite genes into the host phenotype might exist in humans. The best-documented case is that of *Toxoplasma gondii* which establishes persistent infections within the central nervous system of rodents but also in humans (20–80 % of infection, depending on the country). In rats, *T. gondii* provokes an increase in activity, a decrease in neophobic behaviour, and an alteration of the perception of risk; as a result infected rats are easily preyed upon by cats, in which *T. gondii* completes its life cycle. While in humans, although the parasite is in a “dead end host,” it provokes various disorders, including changes in the personality; even the risk of car accidents seems significantly increased in infected people.

Although the question of host manipulation must be regarded with a “critical eye” and the fact that the demonstration of the adaptive value of the host morphological and/or behavioral changes has not always been achieved, it is now widely accepted that the “extended phenotype” is one of the major adaptations facilitating parasite transmission.

Extrinsic Incubation Period (EIP)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the time needed by parasites inside its vector.

Exuviae

From Latin: *exuviae* = detached clothes. This term describes the empty chitinous or horny cover, which is left by, e.g., arthropods or reptiles after molt.

Eye Gnat

The chloropid fly *Hippelates pusio*, which is only 2 mm long, bears yellow legs, eyes, and antennae, makes minute lesions in the conjunctival epithelium and may transmit the agents of contagious conjunctivitis, thus introducing the “sore- or pink-eye disease.”

Eye Parasites

Parasites may enter each organ of the body. Several parasitic stages, however, have developed a special favor for this organ, which of course is especially sensible with respect to human welfare. Table 1 summarizes the parasites found in the different regions of the human eye. The life cycles, morphology, reproduction modes, and the pathological effects are described in the entries on the respective organisms). Figures 1, 2, 3, and 4 show some of the most common aspects of parasites in eyes (pages 506, 507). For eye parasites of animals ► [Nervous System Diseases, Animals](#).

Eye Spot

Several ► [trematodes](#) and especially their larvae possess an optical system to register light and dark in order to find suitable hosts. Since dense pigment surrounds the optic cells, which are protrusions of ganglia of the anterior region or of the midbody and contain microtubuli ► [aberrant cilia](#), the developmental stages appear with dense spots. The number and arrangement of such spots are species-specific.

Eye Worm

Nematodes of the genus ► [Thelazia](#) parasitize in the lachrymal ducts of horses and cattle. Transmission occurs by means of flies of the genus *Musca* that take up larvae 1 from the conjunctiva and introduce finally larvae 3. The mass of larvae 1 block the excretion of the lachrymal fluid. See also ► [Filariidae](#), ► [Loa loa](#), ► [Thelazia](#).

F

Facultative Anaerobes

Name

Greek: *aer* = air, *bios* = life.

These animals may survive also in absence of oxygen; e.g., *Toxocara* worms obtain most of their energy from glycogen degradation.

Fahrenheit' Hypothesis

The common ancestors of modern parasites were themselves parasites of the common ancestors of their present hosts.

Fahrenheit' Rule

Hypothesis that ► [Mallophaga](#) and their bird hosts passed through the same co-speciation and co-evolution, and that thus their phylogeny reflects this.

Fallisia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The genus of haemosporidian parasites, which parasitizes in mature thrombocytes and neutrophils, is found in the peripheral blood of host

species belonging to diverse saurian families (Agamidae, Gekkonidae, Polychrotidae, Scincidae, Teiidae). The following species are described:

In Central and South America:

F. biporcati, *F. dominicensis*, and *F. poecilopi* from lizards of the genus *Anolis*, *F. thecadactyli* from the lizard *Thecadactylus rapicaudus*, *F. simplex* from the iguanid lizard *Plica umbra*, and *F. effusa* and *F. modesta* from lizards *Neusticurus bicarinatus* and *Tropidurus torquatus*, respectively

In Australia:

F. copemani in the skink *Carlia rhomboidalis*

In Thailand:

F. siamense in the flying dragon *Draco maculatus*

In Saudi Arabia:

F. arabica in *Scincus hemprichii*

Fannia

Genus of flies, e.g., *Fannia scalaris* and *F. canicularis* (= i.e., smaller houseflies) look very similar to *Musca domestica*. However, the larvae of *Fannia* spp. have characteristic lateral branches (Fig. 1, page 510). The adults fly without zigzag movements mostly horizontally close to

Fannia, Fig. 1 Larvae of *Fannia scalaris* (left) flies and *F. canicularis* (so-called small houseflies) or toilette.

the ceiling of rooms. Larvae of these flies may be found in the rectum, vagina, or bladder of humans (Myiasis).

Fasciola gigantica

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *Fasciola* = little tape; *giganteus* = extremely large.

Life Cycle

This liver fluke of ruminants and related animals occurs in Africa, Asia, Indonesia, Philippines, and in countries around the eastern Mediterranean Sea. There are found prevalence rates in cattle and water buffaloes of up to 90 %. This worm reaches a size of up to $7.5 \times 1\text{--}2$ cm and has a similar life cycle like ► *Fasciola hepatica* (see Table 1 in ► Trematodes). The eggs look similar to those of *F. hepatica*, but are larger and measure $150\text{--}190 \times 90\text{--}100$ µm. Intermediate hosts are several species of the genus *Radix* (syn. *Lymnaea*).

Prepatent Period

Thirteen to sixteen weeks.

Patency

In cattle mostly 1 year, however, in rare cases also 3–4 years; in buffaloes more than 4 years.

Therapy

Treatment with triclabendazole (10–12 mg/kg bodyweight, oral) was very successful in sheep and cattle to clear infections with young and adult worms.

Fasciola hepatica

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *fasciola* = small band; Greek: *hepai* = liver.

Classification

Genus of Digenea.

Morphology

The life cycle of the so-called large liver fluke is shown in Fig. 1.

Adult worms (20 - 30 mm in length) are characterized by an apical protrusion and a tegument with many toothed hooks (Figs. 2 and 3). The eggs are very large, have an operculum, and can be isolated by the sedimentation technique (Fig. 4).

***Fasciola hepatica*, Fig. 1** Life cycle of *Fasciola hepatica* of humans and of numerous plant feeding animals, ruminants, rabbits, horses etc., which are final hosts (a). The final hosts excrete operculated eggs, within which a ► miracidium stage develops. After hatching in fresh water

this motile stage enters an intermediate host (snails, b), wherein finally typical tailed cercariae develop. These stages swim to waterplants, become attached there, and encapsulate themselves to become a metacercaria, which is ingested by a final host (a)

***Fasciola hepatica*, Fig. 2** Light micrograph (LM) of an adult fluke (a) and higher magnification of the anterior end (b). B = ventral sucker; D = intestinal branch; UE = uterus with eggs

***Fasciola hepatica*, Fig. 3** Scanning electron micrograph (SEM) of the anterior portion of an adult fluke; note the numerous tegumental spines, 2 suckers, and 2 genital openings

Life Cycle

See Fig. 1.

***Fasciola hepatica*, Fig. 5** Macrophoto of a sheep liver with adult *Fasciola hepatica* stages

F

Disease

The large adult worms block the bile ducts and induce severe morphological and physiological malfunctions of the liver of infected animals (Fig. 5).

Treatment

Adult flukes in cattle can be treated with albendazole (7.5 mg/kg bodyweight), netobimin and closantel, larval and adult stages in cattle and sheep by tricalbendazole.

Fascioliasis, Man

Fascioliasis describes an infection of the bile ducts with ► *Fasciola hepatica*, the liver fluke of sheep, cattle, and man. After the ingestion of the metacercaria encysted on water plants (water cress salad), the larvae wander through the wall of the gut, into the liver ► **parenchyma**, and into the bile ducts. The migration tracts are accompanied by an intense inflammatory reaction with prominent eosinophils and Charcot-Leyden crystals, resolving ultimately by fibrosis (► **Pathology**, Figs. 3a, b and 21a, c). The liver may be enlarged and show abnormal function. Blood leukocytosis with ► **eosinophilia** and fever are prominent. After long-standing infection with ► **flukes**, bile duct ► **hyperplasia**, pericholangitis, periportal fibrosis, and obstruction of the bile duct may develop. *F. hepatica* eggs are shed in the stools.

Targets for Intervention

Among the food-borne zoonothropotic parasites, *F. hepatica* deserves attention as its control, seemingly simple, may pose major practical problems, foremost the relatively poor response to treatment and the high probability of reinfection. Upon reaching water the eggs release miracidia which infect aquatic snails. After completing development in the snail host, the infective metacercariae leave the snail and attach themselves to plants and so reach their vertebrate hosts, especially sheep, cattle, and humans. Figure 1 shows the targets of intervention which consist of the elimination of infection and the interruption of the infection cycle. The practical approaches to control include the detection and treatment of vertebrate carriers, the safe disposal of human feces, the avoidance of raw aquatic vegetables and of those grown in wetlands, and as far as livestock is concerned, the avoidance of grazing in wetlands. The control of aquatic snails is a hypothetical possibility rather than a practical proposition.

Fascioliasis, Man, Fig. 1 Targets and approaches for the control of fascioliasis

Main clinical symptoms: Liver infection, fever, dyspepsy, ascites, eosinophilia.

Incubation period: 3–12 weeks.

Prepatent period: 3–4 months.

Patent period: 1–20 years.

Diagnosis: Microscopic determination of eggs (► *Fasciola hepatica*, Fig. 3) in fecal samples by sedimentation method. ► **Serology**.

Prophylaxis: Avoid eating raw freshwater plants.

Therapy: Treatment see ► **Trematocidal Drugs**.

Fascioloides magna

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *Fasciola* = little tape; *magnum* = large.

This so-called American giant liver fluke reaches a length of 10 cm and a width of 3–4 cm and parasitizes in the liver of ruminants in North America (e.g., Cervidae, caribos, elks, bison, and cattle). This species was apparently introduced in Europe by imported animals, since it was found in Austria, Hungary, Croatia, Czech Republic, and Slovakia reaching prevalence rates of 13–90 % in some regions in deer population. Intermediate hosts are snails of the genera *Lymnaea* and *Galba* (*G. truncatula*).

Prepatent Period

Six months.

Patency

Up to 5 years.

Therapy

Triclabendazole (see ► *Fasciola hepatica*).

Further Reading

Fasciolopsiasis

Fasciolopsiasis is an infection of the duodenum and jejunum of humans with adults of ► *Fasciolopsis buski*, Figs. 1, 2. It is usually asymptomatic when small numbers of worms are present. However, the multiple attachment sites that become ulcerated, can lead to appreciable

blood loss and ► *abscess* formation. Intestinal obstruction by large numbers of worms has been reported.

Main clinical symptoms: ► *Diarrhoea*, nausea, ► *vomiting*, ► *oedema*, ► *anaemia*, ascites.

Incubation period: 1–2 months.

Prepatent period: 2–3 months.

Patent period: 1 year.

Diagnosis: Microscopic determination of eggs (► *Fasciolopsis buski*, Fig. 3) in faecal samples (by sedimentation technique).

Prophylaxis: Avoid eating uncooked tropical vegetables or fruit.

Therapy: Treatment with praziquantel, see ► *Trematodocidal Drugs*.

Fasciolopsis buski

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *fasciola* = little tape. Greek: *opsis* = appearance. English: intestinal giant fluke.

Geographic Distribution/Epidemiology

Especially in India, Bangladesh, China, East Asia, Borneo, Sumatra, and Taiwan, about 40 millions of humans are infected. There occur also cases in Europe due to metacercariae being attached at so-called water nuts.

Morphology/Life Cycle

Fasciolopsis buski is the largest trematode parasitizing humans. This worm is up to 7,5 cm long,

2–4 cm wide, and up to 4 cm thick (Fig. 1). The adult hermaphroditic worms are attached by help of their oral and ventral suckers at the wall of the upper region of the human duodenum. They produce rather large eggs ($130\text{--}140 \times 80 \mu\text{m}$) which cannot be differentiated from those of ► *Fasciola hepatica* by means of morphological criteria. When excreted they are unembryonated and only in water they develop inside the typical miracidium larva (Fig. 2). The further life cycle is very similar to that of ► *Fasciola hepatica*; however, the infectious, encysted metacercariae are often attached at the leaves and fruits of the so-called water nut (*Trapa natans* = the swimming one). First intermediate hosts are freshwater snails of the genera *Planorbis*, *Segmentina*, *Hippeutis*, or *Gyraulus*, while the infection finally occurs when humans or some other vertebrates ingest the encysted metacercariae at water plants. The encystation is very protective so that the metacercariae survive transportation of the plants to Europe by ship. In endemic regions, pigs are main reservoir hosts; however, also cats, dogs, and rabbits may become infected, if they ingest metacercariae on plants (Figs. 1–5).

Fasciolopsis buski, Fig. 1 Light micrograph of a stained adult worm of *Fasciolopsis buski*

Symptoms of Disease (Fasciolopsiasis)

Even in case of infections with huge amounts of worms, defined symptoms may be scarce or may even be absent. However, in several cases the following symptoms have been described: nausea, vomiting, diarrheas, and flatulence. In cases of infections with huge numbers of these large worms, which occur mainly in rural regions of the endemic countries, symptoms like anemia, weakness, loss of weight, edemas, and ascites may occur and also some death cases have been described.

Curiosum

A now deceased American female “pseudoscientist” published books describing that this worm is exclusively responsible for HIV disease and for all cancer symptoms. She claimed that her “zapper” – a 6-V battery – sold for about 200 Euro would kill *F. buski* worms and thus

cure both AIDS and cancer at the same time. This evident fraud is still ongoing with successors, since there is no legal means to stop payments between private persons.

Diagnosis

The method of choice is the microscopical determination of the large-sized eggs ($130\text{--}140 \mu\text{m} \times 80\text{--}85 \mu\text{m}$). In cases of huge infections, adults are found in feces or in vomited fluids.

Infection

Oral uptake of encysted metacercariae glueing on leaves or fruits of water plants (e.g., *Trapa natans*) which are also called water caltrop. Repeated infections are common, since immunity is not reached.

***Fasciolopsis buski*,**

Fasciolosis, Animals, Fig. 1 Sheep liver with adults of *Fasciola* in the calcified bile ducts (artificially opened)

F

Fasciolosis of bovines

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the symptoms of infections of bovines with ► *Fasciola hepatica* and related species. Details of life cycle, disease, distribution in Europe, and means are summarized in the Virbac book on *Fasciola hepatica* (edited by Prof. Philippe Dorchies, Toulouse).

Further Reading

- Dorchies P (2007) Comparison of methods for the veterinary diagnosis of liver flukes (*Fasciola hepatica*) in cattle. Bull USA MV-CN, 64/2007 (1-2)

Fasciolosis, Animals

General Information

Disease caused by the ► liver fluke genus *Fasciola*. *F. gigantica* occurs in the tropics. ► *F. hepatica*, the common liver fluke, is the most widespread and important of the group. It is found mainly in sheep and cattle but a patent infection can develop in horses, pigs, wild animals, and in humans (► *Fascioliasis*, Man). The

pathogenesis of fasciolosis is attributable in part to the invasive stages in the liver and in part to the blood-feeding by the adults in the bile ducts (Fig. 1). The process in all hosts shows close similarities, but considerable variation in severity occurs.

Pathology

Ruminants

The pathological manifestations depend on the number of metacercariae ingested. The disease may follow acute or chronic courses. Acute fasciolosis is less common than the chronic entity and is almost invariably seen in sheep. It is essentially a traumatic hepatitis produced by the simultaneous migration of large numbers of adoleoscara. It is towards the end of this development phase, about 6 weeks after infection, that the signs are apparent, with the major losses occurring 7–8 weeks after infection. Death may occur rapidly or after several days. Animals are disinclined to move, are anorexic, and show a distended abdomen which is painful to the touch. This is also the stage of parasitism in which “► black disease” occurs (*Clostridium novii* Type B).

Fasciolosis is most commonly a chronic disease, with no characteristic clinical signs. Loss of appetite and paleness of the mucous membranes appear to be constant features, and submandibular and udder ► oedema are occasionally seen. Jaundice is hardly ever a sign in the living animal.

Chronic debility with vague digestive disturbances are common. There is a substantial effect on milk production, and a reduction in food conversion efficiency with reduced weight gain. A reduction in wool production may occur in sheep, without symptoms of fasciolosis being apparent. Fasciolosis in sheep also has an adverse effect on conception and/or establishment of the fetus.

Changes in serum protein generally take the form of a depression in albumin compared with the globulins. They develop in two stages. The first stage coincides roughly with the period of fluke migration and is characterized by a progressive but usually mild ► [hypoalbuminaemia](#), with a more pronounced hyperglobulinaemia of variable severity. The second stage, which is associated with the presence of adult parasites in the bile ducts, is attended by further deterioration of albumin as well as a progressive reduction in globulin concentrations. There is little disagreement on the cause of the hyperglobulinaemia, which is generally considered to reflect increase synthesis of immunoglobulins in response to parasitic antigens. On the contrary a more complex nature of the different processes and inter-relationships are involved in the pathogenesis of hypoalbuminaemia. During the migratory stage hypoalbuminaemia is brought on by a combination of reduced albumin synthesis and plasma volume expansion. During the biliary stage of the disease the severity of hypoalbuminaemia is related to the loss of albumin into the intestine and to the rate of albumin synthesis and the fractional and total rates of albumin catabolism. These, in turn, are related to the levels of nutrition, appetite, and fluke burden. The increased synthesis of albumin probably diverts available amino acids away from other protein metabolism (muscle, milk, wool), thus accounting for the lowered levels of productivity seen in animals infected with *F. hepatica*.

The ► [anaemia](#) is of the normocytic normochromic type, though some macrocytosis has been reported. The anaemia is well-recognized but its etiology is controversial.

Several factors may account for the anaemia:

- Anaemia in the migratory phase is caused by accidental damage to hepatic vessels and haemorrhages.
- Intrabiliary haemorrhage and consequent loss of red blood cells occur when adults arrive in the bile ducts. The ultimate degree of anaemia is not related to the severity of biliary haemorrhage, but rather to the animal's erythropoietic capacity which is influenced by levels of dietary protein and iron.

Good correlation between the bromsulphthalein excretion test, serum glutamate oxalo-acetate transaminase and gamma glutamyl transferase determinations for the assessment of liver damage are found in infected sheep (liver function test).

Horses

F. hepatica is occasionally found in the equine and camel liver. Heavy infections are rare, and are usually only discovered during post-mortem examination.

Swine

F. hepatica has been found in pigs, but infections are very rare.

Fatigue

Symptom of clinical babesiosis in humans. Babesiosis.

Favorization

Favorization was defined as an adaptation which gives the meeting of a host by a parasite a higher probability than it would have only by chance (i.e., by causes unrelated with transmission). For instance, any process of chemical attraction which provokes the encounter between a larval stage of a parasite and its target host is a favorization process.

Favorization plays a variable role in parasite life cycles but is rarely absent. Although some parasite species invest principally in the production of a great number of infective stages which meet the host by chance, probably a majority of parasites have selected favorization processes in the course of evolution.

The main aspects of favorization are as follows:

- There is a free-living stage which disperses in the environment and exhibits some capacity to “find” the host. This is a simple process and the one most widely used by predators to “find” the prey. However, larval stages of parasites have, in general, limited capacities to localize a suitable host at distance. As exceptions, one must mention the numerous studies carried out on the larval stages of monogeneans and ► [trematodes](#). These researches demonstrate that aquatic larval stages may, to a certain extent, detect chemical gradients of substances emitted by the target hosts. It is surprising that the specificity of the attraction is wider than the specificity of development, with the result that a number of larval stages attach themselves to or penetrate into unsuitable hosts. The loss of infective stages known as “decoy effect” has been envisaged as a method of biological control (introduction of decoy organisms) but without any real success until now. The capacity of locating a host is much more developed when it is the adults, not the larvae or juveniles, which infect the host, as is the case of insect parasitoids. To a high degree, the parasitoids

possess all the sensory organs common in ► [arthropoda](#). Some species detect their hosts, mainly lepidopterans, by odour (sometimes by the odour of the plant on which they feed), by vibrations (sometimes through several centimeters of wood), etc. The capacities of parasitoid insects to localize their hosts are sometimes surprising; possibly the most amazing of all is the wasp *Ichneumon eumerus*, which lays its eggs in a caterpillar (of the genus *Maculinea*) which lives itself in the depth of *Formica* nests. The wasps penetrate only into the nests which do harbour a caterpillar. It is supposed that the wasp listens at the entrance of the nest and is capable of detecting the noise made by the mandibles of the caterpillar. Let us add that the wasp emits a substance which makes the ants fight between themselves instead of attacking the wasp, whilst the latter makes its way to the caterpillar.

- There is a coincidence between the presence of the parasite and the presence of its host in space and/or time. This has been particularly studied in aquatic ► [cercariae](#) of trematodes and microfilariae of nematodes. The coincidence in space is achieved by a particular behaviour: in a same aquatic environment not all the species of cercariae swim at the same depth. Certain species swim rapidly towards the surface, others remain at the bottom, others scan the water column, etc. These different behaviours increase the probability of meeting the convenient target hosts. The coincidence in time is achieved through the emergence of cercariae from the snail intermediate host. In most species, there is a very precise pattern of emergence (see Combes 2003) which is correlated with the activity rhythms of the host. Théron has shown that “chronobiology” of cercariae can be selected rapidly with the result of increasing continuously the probability of meeting the host: in Guadeloupe for instance, *Schistosoma mansoni* has two different hosts; humans and the black rat *Rattus rattus*: in transmission sites where humans are the main hosts, cercariae emerge from snails in the

Favorization,

Fig. 1 Patterns of emergence of *Schistosoma mansoni* cercariae in foci where humans are the main hosts (grey bars, at the back) and in foci where rats are the main hosts (white bars, at the front). Confidence intervals are omitted (Original, data from several papers by A. Théron)

morning or around midday; in transmission sites where rats are the main (sometimes the unique) hosts, cercariae emerge later, at the end of the afternoon (Fig. 1). Microfilariae of ► **nematodes** which live in the blood of vertebrates must be taken by ► **Mosquitoes** or other biting arthropods to pursue their development. Most species aggregate in peripheric vessels at a period of the day corresponding to the time of biting activity of the vector. For instance, 80–100 % of microfilariae of ► *Wuchereria bancrofti* are found in the peripheric blood of humans during the night (i.e., when the principal vector *Culex fatigans* is active) whereas they are virtually absent there during the day. A difference between microfilariae and cercariae is that microfilariae have a long lifespan (several weeks) and migrate to the peripheric vessels every day, whereas cercariae live only a few hours and have only “one chance” to find a host. The rhythm of microfilarial migrations is determined by the variation of physiological parameters of the human body; people working at night show the highest peripheral microfilaremy during the day and constitute probably dead ends for transmission. The rhythm of peripheral microfilaremy is not the same in areas where the vectors have different activity rhythms; in Polynesia, for instance, where the vector *Aedes pseudotellaris* bites during the day, the rhythm is reversed.

- The parasite manipulates the behaviour of its “upstream” host. At any transmission event in the life cycle, the “upstream” host is the host where the parasite comes from. The most astonishing example of a manipulation of the behaviour of the upstream host is that of the trematode *Gynaecotyla adunca*. The snail intermediate hosts live normally at a certain distance from the shore. The presence of larval stages of *G. adunca* provokes an alteration of the snail behaviour, which move towards the nearest beach where the second intermediate hosts (various crustaceans) live, and where the cercariae are emitted.
- The parasite manipulates the behaviour of its “downstream” host. The “downstream” host is the host to which the parasite moves during a transmission event. In contrast with the previous case, this process of manipulation is extremely frequent and intervenes when the parasite is transmitted from a prey to its predator. The parasite provokes various changes in the prey’s behaviour (the upstream host), which make it either debilitated, or more conspicuous, or both. However, it is the behaviour of the downstream host which is manipulated since it is attracted by a prey which is easier to catch, but carries the infective stage of the parasite. A striking and well-known example is that of various species of the trematode ► *Diplostomum*. To become an adult, the

parasite must be transmitted from a freshwater fish to a piscivorous bird: the larval stages (Metacercariae) of the parasites encyst in the eye of the fish, making it blind, and incapable of detecting the predator. In other life cycles, the presence of the parasite provokes an increase of the activity of the intermediate host, which makes it more conspicuous to the predator. Several studies show that the alteration of the behaviour appears only when the larval stage is actually infective. This is the case for the cestode ► *Schistocephalus solidus*, which develops successively in a copepod, a fish (which ingests the copepod) and a piscivorous fish. Both the copepod and the fish exhibit a particular behaviour which makes them more susceptible to predation, but this occurs only when the corresponding larval stages of the parasite are mature. Another example is that of shore crabs whose hiding behaviour at low tide is modified by an acanthocephalan; crabs exposed are at a greater risk of predation by definitive bird hosts. A study demonstrates a different strategy on the part of the parasite: the tapeworm ► *Hymenolepis diminuta* which infects the rats when they ingest the beetle *Tenebrio molitor*, impairs the chemical defense of the insects, which make them more palatable to the rats.

Name

Latin: *filum* = filament; *oideus* = similar

Geographic Distributions/Epidemiology

Worldwide, in cases of farmed animals, local epidemics may occur.

Morphology/Life Cycle

The adult male and female worms are long and rather thin in diameters. They live in different organs depending on the various species. Their larvae are called microfilariae, since they are very long 120–350 µm, but mostly only 6–12 µm in diameter, so that they remain invisible with the naked eye. These microfilariae occur – depending on the species – either in the blood or in the subcutaneous tissues of their hosts. In the peripheral blood, they may be present permanently or only periodically during some hours which correspond with the (flight) activities of their vectors. These vectors belong to a broad spectrum of bloodsucking or skin-feeding arthropods. The different species are listed below according to their vertebrate hosts (see also Tables 1–6):

Symptoms of Disease

The symptoms depend on the location of the adult and larval worms, and the intensity of damages is closely related to the amount of parasites.

or mouthparts of flies when licking at open wounds.

Diagnosis

Microscopical determination of microfilariae obtained (depending on the species) either from peripheral blood or from subcutaneous tissues (see, e.g., ► *Onchocerca volvulus* or ► *Wuchereria bancrofti*).

Prophylaxis

Reduction of potential vectors in the surroundings of animals, application of repellents/insecticides, and/or use of mechanical traps of insects in stables.

Incubation Period

Mostly months.

Infection

Transmission occurs by bites of bloodsucking insects or skin-feeding arthropods (depending on the species) or by mechanical transmission by feet

Prepatent Period

Months to years.

Filariasis, Lymphatic Tropical

Synonyms

Brugiasis; Filariosis; LF; Wuchereriosis

General Information

► **Lymphatic filariasis** is an infection with one of several mosquito-borne filarial worms of the species ► *Wuchereria bancrofti*, ► *Brugia malayi* or *Brugia timori*, which live in the subcutaneous lymphatics or lymph nodes, with larvae circulating in the bloodstream. About one-fifth of the world's population live in areas where lymphatic filariasis is endemic. The disease is worldwide, 110 million people are estimated to harbour such infections. *W. bancrofti* is widely distributed throughout the tropics. *B. malayi* is restricted to parts of Southeast Asia and *B. timori* shows an even more restricted distribution in the Malay Archipelago. Adult *W. bancrofti* is restricted to man, while domestic and wild animals may serve as alternative hosts of *B. malayi* and *B. timori*. *W. bancrofti* is transmitted by *Culex*, ► *Anopheles*, and *Aedes* spp., *B. malayi* and *B. timori* predominantly by ► *Mansonia* spp.

Clinical manifestations of filariasis are almost exclusively due to the microfilariae shed by the adult female worms. The symptoms include initial filarial fever and lymphangitis which later gives rise to recurring lymphoedema. High adult wormload, and consequently high microfilarial density, favours the development of lymphangitis and elephantiasis.

Pathology

The larvae are injected intradermally with a mosquito bite and find their way to the large lymphatics, where they mature and mate. Swelling of lymph nodes containing adults is a common feature. However, when an adult worm dies severe lymphadenitis with chronic inflammatory to granulomatous reaction results, including

eosinophils which ultimately leads to fibrosis. In some multiply infected individuals this may lead gradually to chronic lymphatic obstruction, which in a small percentage of cases progresses to the lymphedematous complication of elephantiasis, usually in an extremity. The newborn larvae circulate in the bloodstream within the internal organs, such as the spleen, and sometimes they migrate cyclically to the peripheral circulation, coincident with the biting/feeding habits of the prevalent transmitting mosquito. Tropical eosinophilic fever with pulmonary infiltration is often attributed to this infection.

Immune Responses

Because of the very long periods of survival of the ► **macrofilariae** (=adult worms) in their hosts (5–15 years), it is obvious, that these parasites must have developed complex mechanisms to evade killing by the host immune defenses. In addition, the host's immune response significantly contributes to the different pathological manifestations of the disease.

There is a broad range of immune reactivity with considerable individual variation. In lymphatic filariasis, microfilaremic individuals (MF) who are clinically asymptomatic have high parasite burdens and little or no parasite antigen-specific cell-mediated responses. In contrast, patients with chronic lymphatic disease, e.g., elephantiasis, typically are amicrofilaremic and vigorous T cell responses against the parasite can be detected.

As for most of the other parasitic diseases, models of filarial infection in inbred mice significantly contributed to the understanding of the disease-influencing immunoregulatory events. Since laboratory mice are not permissive for filarial species found in infected humans, immunity to different stages of these filariae (3rd-stage larvae, adults, and microfilariae) has been analyzed separately as a surrogate approach. On the other hand, in the mouse model of *Litomosoides sigmodontis* infection, the full developmental cycle can be established in inbred mice, allowing to study immunity during maturation of infective larvae into adult worms.

Innate Immunity

Information on the role of components of ► [innate immunity](#) in the early control of filariae is limited. Innate immune responses to *Brugia malayi* and *Onchocerca volvulus* are interestingly initiated by endosymbiotic *Wolbachia* bacteria and are dependent on TLR2, TLR6, and MyD88. In chronic infections however, the observed diminished expression and function of TLR is a likely consequence of chronic Ag stimulation and could serve as a novel mechanism underlying the dysfunctional immune response in filariasis. In a study by Babu et al. an unexpected role of NK cells was described. Comparisons of *B. malayi* worm survival in strains of mice with different levels of NK cell activity showed, that host NK cells are required for the growth of this human filarial parasite. While NOD/LtSz-SCID mice with diminished or absent NK cell activity were non-permissive to worm growth, C.B17 SCID mice with normal NK cell activity were highly permissive. Furthermore, transfer of NK cells into NK-deficient mice rendered these animals permissive. Although the mechanisms by which NK cell allow the growth of filariae is enigmatic so far, these findings clearly point to an interesting role of the innate immune system in the establishment of this parasitic disease. The most compelling evidence for a role of eosinophils in immunopathology of filarial infections comes from analysis of onchocercal dermatitis and keratitis. There is a consistent presence of eosinophils and eosinophil granule proteins at the site of tissue damage, either after parasite death or direct injection of parasite antigens. However, the role of IL-5 and other chemoattractant mediators for the recruitment and activation of eosinophils has yet to be established.

B Cells and Antibodies

High levels of parasite-specific IgE and IgG4 are produced in filariasis patients, generally accompanied by ► [eosinophilia](#). A reciprocal expression of these 2 isotypes has been found in lymphatic filariasis patients, with asymptomatic patients having much higher ratios of IgG4:IgE than found in elephantiasis patients, suggesting either that IgE is an antifilarial antibody, and/or that high IgE is involved in the pathogenetic pathway of the

disease. High quantities of IgG4 can be frequently found in sera of microfilaremic patients, where sometimes up to 95 % of the filarial-specific antibodies are of this subclass. In contrast, in elephantiasis patients IgG1, 2 and 3, dominate the filaria-specific antibody response. It seems likely that these antibodies may contribute to the pathology through ► [ADCC](#) or ► [immune complex](#) formation.

In mice infected with *B. malayi* the clearance of microfilariae was found to be clearly antibody-dependent. CBA/N mice which carry the Xid defect have a pronounced impairment of the B1 cell subset and are therefore unable to develop certain T-cell-independent IgM antibodies. The findings that microfilaremia can not be controlled in these animals after i.v. injection of *B. malayi* or implantation of *A. viteae* gravid females strongly suggest that T cell-independent IgM antibodies to the microfilariae's surface are involved in the clearance of microfilariae.

T Cells

Immunity to most filarial infections is clearly T cell dependent. Nude mice and rats are susceptible to infection with a number of species (*A. viteae*, *B. pahangi*, *B. malayi*) to which their normal, immune competent littermates are resistant, and infection against *B. pahangi* can be established in normally resistant CBA mice when these are deprived of T cells. The resistance of mice to *B. malayi* can be probably mediated by either CD4⁺ T cells or CD8⁺ T cells: Resistance to the maturation of infective larvae (L3) was not abrogated in either β 2-microglobulin knockout mice, which lack MHC class I molecules and class-I-restricted CD8⁺ T cells, or in anti-CD4-treated or CD4-deficient mice.

Important clues for the contribution of Th1 or Th2 cells to pathology or control of the parasite came from analysis of onchocerciasis patients. In individuals with generalized infections characterized by high microfilarial loads, low proliferative T cell responses to parasite antigens is accompanied by a production of Th2 cytokines. On the other hand, a minority of patients able to prevent maturation of L3 displays an immune response characterized by the predominance of IFN- γ producing Th1 cells. Several experimental studies

have been performed to analyze the relative contributions of Th1 and Th2 cells and their products (cytokines) to the control of filarial parasites in mice. Following infection with L3 or immunization with L3 there is a strong expansion of parasite-specific Th2 cells and of associated immune responses such as IgE production and eosinophilia. In infections with both ► *Brugia* and *O. volvulus* the Th2 responses appear to be protective, since antibodies against IL-4 or IL-5 resulted in longer survival of larvae. However, resistance to maturation of L3 into adults was not abrogated in IL-4 knockout mice, arguing for compensatory mechanisms in these gene-deficient mice. Infection of BALB/c mice with adult *B. malayi* worms, especially females, also induced strong IL-4 production by splenocytes.

The Th cell response to microfilariae has been most extensively investigated using *A. viteae*, *B. malayi*, *O. volvulus*, and *O. lienalis*. Interestingly, a dominant Th1 response has been observed during the first 2 weeks of infection, which is followed by an enhanced induction of IL-4 and IL-5 in addition to IFN- γ during the subsequent weeks. Thus, the time of exposure to microfilarial antigens seems to drastically influence the type of Th cell response. Both Th cell subsets may significantly contribute to the control of microfilariae, since both IFN- γ -stimulated macrophages as well as IL-5-dependent eosinophils are operative against microfilariae. Activated macrophages are able to damage microfilariae by releasing NO. In addition, microfilariae of some species (e.g., *O. lienalis*) but not of others (*B. malayi*) are sensitive to H₂O₂ which may be produced by eosinophils.

Filaria nematode infection is associated with a profound downregulation of the host immune system. When mice are infected with *B. pahagi*, natural T_{reg} expand and suppress excessive Th2 responses. In a model of murine filarial infection, the infection and subsequent immunosuppression is associated with accumulation of T_{reg} in the thoracic cavity.

Shaping of the Immune Response by the Parasite

Recent reports suggest that filarial parasites have the capacity to actively shape their

immunological environments in their host. For example, secreted products of the ► *nematodes* have been found to differentially modulate the expression and activation of protein kinase C isoforms in B lymphocytes. Furthermore, the expression of CD23 on human splenic B and T cells and Th2 responses are enhanced by soluble products of the parasite. Pastrana et al. cloned homologues of the mammalian migration inhibitory factor (MIF) from *B. malayi*, *W. bancrofti*, and *O. volvulus*. The effects of recombinant forms of the parasite MIF and human of inflammatory and T cell responses by filarial MIF could provide the parasite with a survival advantage.

Planning of Control

The approaches to the control of lymphatic filariasis were formerly based on the elimination of infection by treatment (diethylcarbamazine = DEC) and ► *vector control* for the prevention of infection. Both approaches were only marginally effective due to the poor macrofilaricidal activity of DEC and constraints of controlling *Culex* spp. in urban areas and *Anopheles* spp. in the rural environment. Moreover, the first dose of DEC may cause severe and even fatal adverse reactions in persons infected with ► *Loa loa*, a tissue-dwelling filaria occurring in tropical Africa.

The control of lymphatic filariasis has been revolutionized by the finding that a single dose of ivermectin or DEC or both will eliminate microfilaraemia for several months due to an action against microfilariae and embryonic stages. Although recurring, microfilaraemia will stay below 1 % of the initial level for a year or more. With repeated dosing, once a year, microfilaraemia will not reach the level at which it could cause lymphoedema or elephantiasis. Essentially the same applies to onchocerciasis with regard to the prevention of irreversible ocular lesions. The reduction of microfilarial rates and densities will also lead to a rapid reduction of disease transmission, more effective than it could ever be expected from vector control.

Filariasis, Lymphatic Tropical, Fig. 1 Targets and approaches for the control of bancroftian filariasis

Filariasis, Lymphatic Tropical, Fig. 2 Giemsa-stained anterior end of a microfilaria of *Wuchereria bancrofti*

Filariasis, Lymphatic Tropical, Fig. 3 Giemsa-stained sheath of 2 microfilariae of *Brugia malayi*. E, erythrocyte, N, nucleus, SH, sheath, SZ, nucleus-free zone of microfilaria

Based on these findings, the WHO has embarked on the global elimination of lymphatic filariasis through the annual single dose administration of a combination of ivermectin and DEC to all persons (approximately 1,100 million) residing in areas where the disease is endemic. There is still the caveat of adverse reactions to DEC in people infected with *Loa loa* (► [Loiasis](#)), but this only applies to tropical Africa and can be overcome by using ivermectin alone. The other, yet unknown, factor is the potential role of animal reservoir as an obstacle to the ultimate elimination of human brugian filariasis.

Targets for Intervention

The infective larvae of ► *W. bancrofti* leave the arthropod vector at the time of a blood meal, slide along the outer surface of the ► [proboscis](#) stem, and actively enter the bite wound. After reaching

the lymphatic target organ, they will become adults and mate. The females will produce microfilariae which will periodically or subperiodically enter the blood stream from where they can be taken up by the vector. Figure 1 shows that the detection and treatment of infected persons, suppression of microfilaraemia, vector control, and the interruption of contact between man and vector are potential approaches to the control of ► [bancroftian filariasis](#).

Main clinical symptoms: Lymphangitis, unfeelingness of skin portions; later: chylurie, elephantiasis, i.e., giant swelling of organs.

Incubation period: 3–16 months.

Prepatent period: 7–24 months.

Patent period: 8–10 years (adults live until 18–20 years).

Diagnosis: Microscopic analysis of smear preparations or of membrane filtered material (Figs. 2 and 3); microfilariae are found at 10 p.m. in the peripheral blood, ► [Serology](#).

Prophylaxis: Avoid bites of vector ► [mosquitoes](#) in endemic regions.

Therapy: Treatment see ► [Nematocidal Drugs, Animals](#), ► [Nematocidal Drugs, Man](#).

Filariidae of animals

Filariidae of humans

Filariidae of Humans

The filariidae of humans (Table 1) are still today a big health problem in the tropics, since their chemotherapy is not satisfying and the chance to get infected is still very high, since in the endemic regions many species of efficacious culicoid vectors (Fig. 1) occur in huge numbers and thus cannot be controlled sufficiently. Furthermore, the microfilariae (Fig. 2) of the relevant species stay for a long time in blood, respectively, in the subepidermal tissues of humans and thus can easily be ingested by the relevant mosquito species, which serve as true intermediate hosts (Fig. 1) and vectors. Important species are ► *Brugia malayi*, ► *Dirofilaria immitis*, ► *Dirofilaria repens*, ► *Loa loa*, ► *Mansonella perstans*, ► *Mansonella ozzardi*, *Mansonella streptocerca*, ► *Onchocerca volvulus*, and ► *Wuchereria bancrofti* which are separately presented as well as common symptoms of disease filariasis (Figs. 3, 4, and 5).

Filariidae of Animals

See Table 2.

Filariidae, Fig. 1 (continued) may induce blindness. 1 Visible signs of disease. 2 Microfilariae; the shape (2.1), structure (2, 2.2), and diurnal occurrence are species specific: They may or may not be sheathed (2.2); their terminal nuclei have a species-typical appearance (2, 2.2); they can be found in blood vessels (*Loa*, ► *Brugia*, ► *Wuchereria*) or in lymphatic gaps (► *Onchocerca*); their occurrence in the peripheral blood can be periodical (*Loa*, during the day; *Wuchereria* during the night; some subperiodic strains also exist) or may not be (*Onchocerca*, always present, but in lymph vessels). 3 Intermediate hosts: Depending on the periodic appearance of microfilariae in the host's skin, insects with different biological behavior are involved as vectors (► *vector*, ► *mosquitoes*). Daytime-feeding vectors (deerflies, ► *Chrysops* species, ► *blackflies*, ► *Simulium* spp.) transmit *Loa loa* or *Onchocerca volvulus*, whereas night-feeding mosquitoes (*Aedes*, *Culex*, ► *Anopheles*) may be

vectors of the nocturnal strain of *Wuchereria* and *Brugia*. When microfilariae are ingested by intermediate hosts during the blood meal, they penetrate the intestine and enter the abdominal cavity and the thoracic muscles. After a molt, the L₂ is formed, which has a stumpy shape (sausage stage). Another molt finally leads to the filariform infectious L₃. 4–5 L₃ reaches a length of about 1.5 mm and migrates to the ► *proboscis*, from which they escape when the vector is feeding. They enter the skin through the wound channel made by the biting insect (5, *arrow*). Inside the final host (man), the larvae migrate until they reach their favorite site of location, where they mature (after another 2 molts) within 1 year (prepatent period; ► *nematodes*) (AD = adult worms (in section); AN = anus, E = esophagus; ER = erythrocyte; IN = intestine; L₃ = third larval stage; N = nuclei (their arrangement at the poles of microfilariae is species specific); SH = sheath) (eggshell)

Filaroides Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: *filum* = filament; *oides* = similar.

Geographic Distribution/Epidemiology

Worldwide, widely spread in dog-breeding houses (Europe, USA).

Morphology/Life Cycle

The species *F. marti* (in marten) and *F. hirthi* (in dogs) live as adult worms (♀ = 15 mm, ♂ = 3–5 mm) in the parenchymal region of the lung and in nodules in the tracheal wall. The females depone ovoviviparous eggs, from which larva 1 already hatches inside the lung. After a passage via the trachea, they pass the esophagus and are excreted with the feces. While *F. marti* needs an intermediate host (snails), wherein the infectious larva 3 is formed, *F. hirthi* has a direct life cycle. In this species, larva 1 is already infectious for dogs if they swallow eggs from their own or foreign feces. Larvae 1 enter the intestinal wall and are transported via the bloodstream to the liver. From there, they migrate via the lymph vessels into the lungs, where they reach maturity within 5–6 weeks.

Symptoms of Disease

While immunocompetent dogs mostly show no or only slight symptoms of disease, immunocompromised or very young dogs may become severely affected due to pneumonia, which may cause death.

Diagnosis

Microscopical investigation of larvae obtained by the help of the ► [Baermann](#) method. However, in cases of irregular excretion of such larvae, diagnosis often fails.

Infection

Oral uptake of larva 1 containing eggs or ingestion of free larva 1 (*F. hirthi*) or by feeding of intermediate hosts containing larvae 3 (*F. marti*).

Prophylaxis

Very difficult, since self-infections are possible if feces are not regularly removed. Best method: chemoprophylaxis = repeated application, e.g., of albendazole or of macrocyclic lactones.

Incubation Period

If symptoms occur at all: 1–5 days.

Prepatent Period

Five to seven weeks.

Patency

No definitive data available, but due to self-infections, dogs may be permanently infected.

Therapy

Application of fenbendazole (50 mg/kg bodyweight daily for 3 weeks) or albendazole (2×50 mg/kg bodyweight, orally on 5 days).

Hymenolepid tapeworm (Cyclophyllidea) of chicken and other birds (mostly geese and water birds), which reach a length of up to 40 cm. The scolex is very small; however, a large pseudoscolex is present. The excretion systems consist of six longitudinal channels. Within each segment only a single set of male (three testes) and female organs is present. The genital porus is laterally situated only at one side (unilaterally). Intermediate hosts are crustaceans, wherein the ► [cysticercoid](#) larva is formed.

The Cuban physician J.C. Finlay was the first to recognize and to proclaim in 1881 that the agents of the so-called ► [yellow fever](#) disease are transmitted by bites of ► [mosquitoes](#) (genus *Aedes*). This revolutionary insight was followed by the recommendation to start control measurement at breeding sites of mosquitoes in order to fight against the transmission of yellow fever. His at first belauded theory and its relevant applications were confirmed about 20 years later by the ► [Walter Reed Commission](#). Finlay became the Chief Health Officer of Cuba from 1902 to 1909 and was awarded the National Order of the Legion of Honor in France in 1908. Although being proposed seven times for the Nobel Prize for Physiology or Medicine, this honor was never awarded to him.

Five Days Fever

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Disease due to lice-transmitted ► *Bartonella* bacteria; synonym to Trench fever.

Fixed Pore

A fixed pore is a protein structure that stretches through the ► [cell membrane](#). The molecules to be transported pass through the space, or through a channel formed between the subunits of the pore (► [Membrane Transport](#)).

Flagella

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Many ► [Protozoa](#) use flagella or ► [cilia](#) as locomotory organs. These structures are constructed according to a common plan. While flagella are longer and generally less numerous than cilia, their basic structures are similar (Figs. 1, 2, and 3; see also ► [Blastocrithidia Triatomae](#)/Fig. 2e, Gametes/Fig. 6, ► [Pellicle](#)/Fig. 1c, ► [Trichomonadida](#)/Fig. 1a). Both types of organelle are c. 0.2–0.4 µm in diameter and both possess an ► [axoneme](#) (an arrangement of 9 pairs of outer microtubules and a single pair of central microtubules) that is anchored to a basal body (Kinetosome) that resides inside the cortical ► [cytoplasm](#) of the cell (Fig. 1c, ► [Trypanosoma](#)/Fig. 5b). The ► [basal bodies](#) are similar to

centrioles in having 9 sets of 3 microtubules arranged in a ring-like pattern. The basal bodies may be connected to filamentous elements such as the kinetodesmal filaments of cilia. Several species of Protozoa have a rod-like structure consisting of a network of protein filaments inside the flagellum (Fig. 1d, e). These rods lie beside the axoneme, probably adding to the thickness and stability of the flagellum. This enhancement may be particularly important for Protozoa living in viscous media such as blood or intestinal fluids. Although flagella and cilia are constructed according to a general blueprint, in different Protozoa the paired outer microtubules in the flagella and cilia may differ in shape. The A-tubule, which is furnished with 2 dynein arms, typically possesses 13 protofilaments, whereas the B-tubule has only 9 protofilaments and shares 3 or 4 of the protofilaments of the A-tubule. The dynein arms act as enzymes for breaking down ATP and are assumed to represent the motor system in the gliding-filament theory. This theory postulates that the movement of flagella and cilia is initiated by the gliding of microtubules along each other using the dynein arms as linking elements. The central regions of flagella are stabilized by spike-like elements, in addition to the rod. In the trichomonads and in the trypomastigote stages of trypanosomes, a flagellum may be connected to the cell surface by ► [desmosomes](#) (► [Trypanosoma](#)/Fig. 5b). The recurrent flagellum is attached in this manner and when it pulls the plasma membrane away from the body, the ► [undulating membrane](#) is created (► [Trichomonadida](#)/Fig. 1c). The recurrent flagella never run inside the cytoplasm, but the axonemes of *Giardia* ► [trophozoites](#) run inside the cytoplasm for several micrometers (Fig. 3).

Flagellol®

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This anti-protozoan product clears infections of fish inside aquaria from infections with flagellates such as ► [Spironucleus](#) species, ► [Hexamita](#) species, *Trichomonas* species, *Bodomonas* species, ► [Cryptobia](#) species and *Protoopalina* species.

Warning: Use only for Osteichthyes (= bone fish).

Contents: 140 mg 5-nitro-1,3-thiazol-2-ylazan per ml for use in aquaria.

Dose: 1 ml Flagellol for 40 l water.

Use: See explanation on the label of the bottle.

Producer: Fa. Alpha-Biocare GmbH, Düsseldorf, Germany (www.alphabiocare.de).

Seller: Fa. Sera, Heinsberg, Germany (www.sera.de).

Flaviviridae

Classification

Family of RNA viruses, transmitted by arthropods
► [Arboviruses](#).

General Information

Positive-sense single-stranded RNA viruses (spherical, with envelope); about 60 species.

Important Species

► [Flavivirus](#).

Flavivirus

Classification

Genus of Viruses including some ► [arboviruses](#).

General Information

Positive-sense single-stranded RNA viruses (spherical, with envelope). Altogether about 60 virus species (some of them with several types/subtypes) described. Presently these species are assigned to three main divisions: Tick-borne viruses (with 2 groups), mosquito-borne viruses (with 7 groups), and viruses with no known arthropod vector (with 3 groups).

Important Species

Table 1.

Flavivirus, Table 1 Arboviruses VI. Positive sense, single-stranded RNA viruses: Family Flaviviridae, Genus *Flavivirus*

Serogroup (no. of known members)	Species (selected)	Arthropod host	(Main) vertebrate hosts	Distribution	Disease in man	Disease in animals
Tick-borne group (14)	Tick-borne encephalitis, European, Siberian, Far Eastern subtype	Ixodidae (<i>Ixodes ricinus</i> , <i>Ixodes persulcatus</i> , and other species and genera)	Rodents	Northern and Central Europe, Northern Asia	Tick borne encephalitis, Central European encephalitis, Russian spring summer encephalitis (fever, encephalitis)	Neurological disease

Flea Allergy Dermatitis (FAD)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Allergic reaction due to injection of even smallest amounts of flea saliva. A sensitized animal in general may show two types of reactions:

1. A humoral reaction (= immediate hypersensitivity reaction of type I) occurs within a few minutes after the bite due to intensive histamine excretion.
2. A delayed cell-mediated reaction (= hypersensitivity of type IV), which causes heavy pruritus, loss of hair, and (occurrence) various lesions.

Flea Bites

Fleas can be easily disturbed during their blood meal. Thus they bite again in close neighbourhood to the first bite leading to “rows or chains” of bites (Figs. 1 and 2). Scratching may inoculate bacterial (Fig. 2). In some persons/animals flea bites may introduce severe flea allergy dermatitis (► FAD).

Flea Bites, Fig. 1 Three flea bites in a row

Flea Bites, Fig. 2 Flea bites with bacterial superinfections

Flea Control Never Ending Story

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Since only 1–3 % of a flea population is on dogs and cats and the rest (eggs and larvae) lay/creep on the floor, successful persistent flea control is difficult, especially since resistances had been developed by adult fleas. Thus, Halos et al. (2014) recommend urgently to establish a fixed treatment scheme involving both treatment of animals and

Flea Control Never Ending Story, Table 1 Molecules used for flea control in veterinary medicine (after Halos et al. 2014)

Chemical group	Molecules	Mode of action
Adulticides		
Organophosphates	Diazinon, fenthion	Cholinesterase inhibitors; stimulation of nerve cells
Carbamates	Carbaryl, propoxur	Cholinesterase inhibitors; stimulation of nerve cells
Pyrethroids	Permethrin, deltamethrin, flumethrin	Fixation on sodium channels; stimulation of Na ⁺ entry in nerve cells; hyperexcitation of nerve cells
Phenylpyrazoles	Fipronil, pyriprole	Fixation on both GABA and glutamate receptors of chloride ion channels; blockage of Cl ⁻ entry; hyperexcitation of nerve cells
Chloronicotinyl nitroguanidines, neonicotinoids	Imidacloprid, dinotefuran, nitenpyram	Stimulation of nicotinic acetylcholine receptors; stimulation of postsynaptic neurons
Spinosyns, macrocyclic lactones	Spinosad, spinetoram	Stimulation of nicotinic acetylcholine receptors; stimulation of postsynaptic neurons
Oxadiazine	Indoxacarb	Sodium channel antagonist; paralysis and death
Semicarbazone	Metaflumizone	Sodium channel antagonist; paralysis and death
Macrocyclic lactones (ivermectin/milbemycin)	Selamectin	Fixation on glutamate receptors; stimulation of Cl ⁻ entry; inhibition of nerve cell activity
Isoxazoline	Afoxolaner, fluralaner	Fixation on GABA and glutamate receptors of chloride ion channels of the synapses; blockage of Cl ⁻ entry; hyperexcitation of nerve cells
IGR (insect growth regulator)		
Juvenile hormone analogs	S-methoprene, pyriproxyfen	Decrease reproductive output; reduced egg hatch; mortality at last molt from larva to pupa stage
Organofluorines – benzoylureas	Lufenuron, flufenoxuron	Chitin synthase inhibitor; inhibits egg hatching; induces mortality during molting

elimination of flea larvae on the floor at the same time. The available adulticides and larvicidal compounds are listed in Table 1.

Flea-Borne Human Diseases

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. Black Death, Bubonic Disease

Name

Latin: *pestis*; Engl.: plague; French: peste, bubonic maladie; Span: la peste; German: Schwarzer Tod, Pestilenz; Portuguese: peste.

Epidemiology

Today, there are focally herds of plague bacteria in rodents on all continents, from where occasionally outbreaks among humans had taken their origin (Eskey and Haas 1940; Gage and Kosoy 2005; Hinnebusch 2005; Wilder et al. 2008).

Agent of Disease

Yersinia pestis is a 1–2 $\mu\text{m} \times 0.5 \mu\text{m}$ -sized, gram-negative, aerobe (facultatively anaerobe), flagella-less, rod-like bacterium which might also produce short chains and capsules, which may help to survive in dried blood and in flea feces. When coloring these rod-like bacteria, both of their poles are stained.

Hosts

In nature these bacteria propagate in rats and other rodents.

Symptoms of Disease

- (a) *Bubonic plague*: This form of disease occurs in 80–90 % of the infections and starts 2–7 days after an infection by a fleabite with a primary blister at the infection site containing fluids and masses of the bacteria and then follows sudden fever with chills, strong headache, and regional swelling of lymph nodes. Typically the formation of large, open bubonic swellings reaching infection sizes of a chicken egg follows. As soon as the bacteria enter the inner organs, inner lesions occur and severe bleedings follow. Typical symptoms are cough and black/blue color of the skin, which led to the name “black death” of the whole disease. In untreated cases, 50 % of infected persons die within 7 days, but only 10–15 % if treated.
- (b) *Septicemic plague*: In this case, the infections start with skin lesions (little wounds), which had come into contact to bacteria-containing blood of patients or that of infected rodents. Here occurs finally the same follow-up of symptoms as in the case of bubonic plague. 100 % of untreated people die, 30–50 % of treated ones.

- (c) *Pneumonic plague*: The infections in these cases are acquired by inhalation of plague bacteria expectorated by patients with a severe lung infection. The progress of the disease is very quick and introduces highest lethality rates, reaching (even today) 90 % of the cases within a few days. Often, 10–20 % of treated people died.

Transmission

The bacteria are transmitted by fleabites (more than 30 species are known as efficacious vectors), by contact of skin lesions with bacteria, and/or by inhalation of bacteria from infected people. Furthermore, infection is possible by eating infected undercooked rodents (e.g., guinea pigs in South America).

Diagnosis

Microscopy of fixed and stained bacteria taken from infected sites or from blood agar cultures at 25–28 °C; ELISA.

Therapy

Streptomycin (30 mg/kg body weight), tetracyclines; all have to be given for 10 days.

Legal Regulations

Patients have to be announced to health authorities, which will command strict quarantine to avoid severe outbreaks. In laboratory, the bacterium has to be kept under S3 biohazard conditions.

Prophylaxis

Ban rats and fleas from human surroundings. Use insecticidal repellents while walking in nature.

2. Tularemia

Name

German: Lemmingfieber, Hasenpest; Engl.: deer fly fever, rabbit, hare fever, Ohara disease; Indian: yatobo.

Epidemiology

Reservoir hosts are rodents, roe deer, raccoons, hares, etc. – all living in the northern hemisphere. Thus, human cases occur exclusively in these regions.

Agent of Disease

Francisella tularensis (occurring in four subtypes) is a short, nonmotile, coccoid to rod-like, gram-negative, aerobic bacterium, which reproduces in host macrophages but is also very stable in mud and/or animal carcasses. The infection dose is very low – 10–15 single bacteria stages may be sufficient.

Hosts

See epidemiology.

Symptoms of Disease

One-third of the infections remain without symptoms, while in the rest the following symptoms may occur within an incubation period of 3–10 days and rarely up to 21 days (Neumeister et al. 2009; Löscher and Burchard 2010):

- (a) Necrotic lesions at biting sites (if arthropod transmitted)
- (b) Chilling fevers
- (c) Headache and general weakness
- (d) Lymphadenopathy
- (e) Pneumonia
- (f) Vomiting
- (g) Hepatosplenomegaly
- (h) Rare meningitis cases and intraocular or oropharyngeal lesions
- (i) Lethal cases after septic shock (in 2–3 % of infections)

Transmission

Bites of bloodsucking arthropods (ticks and insects including fleas), contact to reservoir hosts (see above).

Diagnosis

- (a) Microscopy of fixed and stained bacteria,
- (b) bacterial cultures of blood agar show within 3 days colonies of 2–4 mm in diameter, and
- (c) serological antibody detection.

Therapy

Streptomycin for 7–10 days (20 mg/kg bodyweight) and gentamicin 2×2.5 mg/kg bodyweight/day.

Legal Regulations

Diagnosis and culture in laboratories to be done exclusively in personal protected systems.

Prophylaxis

Avoidance of tick and insect bites by repellents and handling of dead wild animals only with gloves.

3. Flea Spotted Fever

Name

Named after Howard Taylor ► [Ricketts](#) (1871–1910), an American scientist who died as a consequence of an infection with the agent of the “Rocky Mountain spotted fever.”

Epidemiology

The agent of disease uses as main hosts cats (Lat: *felis* = cat) and rodents and is found in the Americas, but also in Europe, North Africa, and Asia (Reif and Macaluso 2009; Richter et al. 2002).

Agent of Disease

Rickettsia felis is a small, only 0.8–2 µm-sized coccoid, rod-like bacterium, which reproduces obligatorily in cells (in cytoplasm and nucleus).

Hosts

Cats, rodents, but also humans.

Symptoms of Disease

After an incubation period of 1–2 weeks, fever, muscle pain, headache, and maculopapillary exanthema (in more than 50 % of the cases) occur; however, lethality was found in less than 1 %.

Transmission

Fleabites, however, mostly no eschar-like skin lesions occur at the biting site.

Diagnosis

Serological methods and PCR.

Therapy

Doxycycline.

Legal Regulations

Nothing special.

Prophylaxis

Avoid human flea infestation and protect cat by repellents from fleas.

occur; however, lethality was found in less than 1 %.

Transmission

Fleabites, however, mostly no eschar-like skin lesions occur at the biting site.

Diagnosis

Serological methods and PCR.

Therapy

Doxycycline.

Legal Regulations

Nothing special.

4. Murine Spotted Fever**Name**

The name spotted fever has its origin in aspects of the skin of patients that shows spots of yellowish exanthema.

Epidemiology

This agent of disease is endemic worldwide in many countries: in the USA, the animal hosts are opossums; in other countries such as North Africa, Mediterranean region, South Russia, India, Thailand, Malaysia, Japan, Indonesia, and Australia, it occurs in rats and other rodents. Vectors are many flea species.

Agent of Disease

Rickettsia typhi (syn. *R. mooseri*) develops exclusively in the intestinal cells of their arthropod hosts (including fleas). They are excreted within the feces of the fleas and enter the skin of the vertebrate host mostly at scratching sites. They live strictly intracellularly and are coccoid, rod-shaped bacteria with a size of 0.5–0.8 µm (Neumeister et al. 2009; Löscher and Burchard 2010).

Hosts

Rodents, cats, dogs, and humans.

Symptoms of Disease

After an incubation period of 1–2 weeks, fever, muscle pain, headache, and maculopapillary exanthema (in more than 50 % of the cases)

Prophylaxis

Avoid human flea infestation and protect cats and dogs in households by repellents from fleas.

5. Bartonellosis**Name**

This group of bacteria was named in honor of the Peruvian scientist Alberto Leonardo Barton, who also described *B. bacilliformis* (1909, Carrion's disease in South America) and *B. quintana* (1915, trench fever, Wolhynic fever) (Löscher and Burchard 2010).

Epidemiology

The flea-transmitted *Bartonella* species occur worldwide and are transmitted by fleabites and via contact to flea feces. There are also sand fly-transmitted *Bartonella* diseases, e.g. ► [Verruga disease](#) and ► [Bartonellosis](#).

Agent of Disease

B. bacilliformis (Carrion's disease), *B. henselae*, *B. koehlerae*, *B. dashiae*, *B. clarridgeiae* (all diseases are named cat-scratch diseases), and *B. vinsonii* (bacterial fever) (Billeter et al 2008; Breitschwerdt et al. 2005, 2007; Chomel et al. 1996; Azad et al. 1997; Rolain et al. 2003; Schmidt 1998).

Hosts

Cats, rodents, and humans.

Symptoms of Disease

High fever and additional skin lesions (depending on the species). In cases of the cat-scratch disease due to *B. henselae*, papulae are developed at the biting site within 3–10 days. Furthermore, adenopathies are accompanied by fever. Only rarely severe symptoms occur.

Transmission

While *B. bacilliformis* is mainly transmitted by phlebotomid mosquitoes (*Lutzomyia* species), it also might be transmitted like other species (e.g., *B. henselae*) by fleas.

Diagnosis

PCR and microscopy of biopsies of lymph nodes.

Therapy

Azithromycin in low symptomatic cases, doxycycline (2×100 mg/day) for 4–6 weeks in severe cases and in cases with retinitis.

Legal Regulations

Nothing special.

Prophylaxis

Keep your cats free from fleas; keep away rats from houses.

Erysipelothrix rhusiopathiae**Name**

Greek: *erythros* = red, *pelos* = mud; German: Rotlauf; Engl.: red skin (of pigs).

Epidemiology

This pathogen – identified in pigs about 100 years ago – is found in many mammals (including humans) and birds.

Agent of Disease

E. rhusiopathiae is a facultative anaerobic, gram-positive, rod-like bacterium, which reaches enormous sizes of 0.8–60 µm in length. It may persist

outside a body for a long time, e.g., in remnants of feces (Neumeister et al. 2009).

Hosts

Pigs, humans, many mammals, and birds.

Symptoms of Disease

Painful inflammation of weak body regions with blue-red coloring and additional swellings of the lymph nodes. Infections of humans last mostly about 3–4 weeks.

Transmission

Mainly oral uptake of agents of disease, but also skin contact and meanwhile proven transmission by fleabites and their feces.

Diagnosis

API and VITEK products as well as PCR system from pig control, cultures.

Therapy

Penicillin and cephalosporin.

Legal Regulations

Farm workers have to stop contact with pigs while bearing symptoms.

Prophylaxis

Avoid contact with pig feces and fleas.

General Information

Of the approximately 2,500 species of fleas, about 94 % suck on mammals, the remaining on birds. If they are hungry, many species probe on any warm-blooded vertebrate. Whereas larvae feed on organic material in the nest or lair of the host, adult males and females are obligate bloodsuckers and may live up to 12 months. Fleas can transmit various pathogens due to their repeated sucking activity on different hosts (Table 1), but are mainly known as vectors of ► [plague](#).

The life cycle proceeds as ► [holometabolous development](#) (Fig. 2), including three detritus-feeding larval stages and a ► [pupa](#) in a ► [cocoon](#), within which the finally formed adult fleas can rest for a long time (6 months), e.g., until a bird's nest is settled again or the material re-used. Adults are brown, wingless, laterally flattened, and about 1–6 mm long, jumping away if there is a risk of being caught. Since fleas react super-sensitively, several punctures are usually made by a single flea in the course of blood meal.

Important Species

Table 1.

Distribution

Fleas occur worldwide.

Morphology

The relatively small, rounded head of fleas has often ventral, heavily sclerotized outgrowths, the ctenidia and in some nest fleas no eyes or lateral ocelli. The antennae are very short (three main segments), recessed in deep grooves. The ventral mouthparts consist of three stylets, a pair of maxillary laciniae, and the unpaired epipharynx, held by the five-segmented labial palps. The ► [cuticle](#) is tough and difficult to rupture. The dorsal sclerites of the three thoracic segments overlap the respective following one, and there they often

Fleas

Classification

Order of ► [Insects](#).

Synonyms

Morphology

Figures 1, 2, 3, 4, 5, 6, and 7.

Fleas, Fig. 1 Diagrammatic representation of heads of some important fleas (Table 1). The occurrence of combs (*PC*, *GC*), the arrangement of setae (*SE*) and the shape of the antenna (*AT*) are specific. *AG* antennal groove, *AT* antenna, *CA* caput, *GC* genal comb (with several spines), *OC* ocellus, *PC* pronotal comb (with several spines), *PR* pronotum, *SE* seta

possess many spinelets, the first of which is often a comb of ctenidia. The legs are long, well-developed for jumping, and bear strong claws. Each of the eight abdominal segments also overlaps the following one, often possessing many spinelets there which help to anchor the flea in the fur. In addition to the ctenidia, species can be identified by the genital organs, visible through the cuticle of the last segment, especially in specimens that were cleared chemically and mounted on microscope slides. Males and females can be separated according to the shape of the abdomen, genital organs, and the copulatory apparatus of males. The larvae are elongated and worm-like, without eyes and with legs possessing long setae on the body. Mature larvae are 4–10 mm long. Pupae develop in a cocoon, which is spun by the larvae, and to which dust adheres (Figs. 2 and 5).

The female sand flea (*Tunga penetrans*) penetrates into the skin (► [Jigger](#)).

Genetics

Variations in the biology of different populations of *Pulex irritans* indicate that it is not a single species, but a species complex.

Reproduction

Breeding in the laboratory is possible for many species, especially for fleas of cats and rodents, but labour-intensive. Usually the living host is necessary, except for a strain of the cat flea which has adapted to artificial feeding with cow blood.

Fleas, Fig. 2 (a–d) Life-cycle stages of fleas; the larva (c), which hatches from a 0.3–0.5 mm egg (b), has no eyes and reaches a length of 4–10 mm when fully grown. There are usually three larval instars, but only two in *Tunga penetrans*. Larvae feed on organic debris and on undigested blood from the feces of adults. The differentiated third-stage larva constructs a loosely woven cocoon (3 × 1 mm) which may become encrusted by sand (d).

Inside, the flea pupates (pupa shows anlagen of extremities (d), and remains quiescent until it emerges as an adult (females emerge 3–4 days before the males). Both males and females feed exclusively on blood and may live up to 12 months. AT antenna, OM ommatidium (ocellus), PG pygidium (sensillum), SE sand-encrusted cocoon, ST stigma (spiracle)

Adults copulate immediately after emergence from the cocoon. Beginning 1 or 2 days later, females lay several hundred eggs (0.3–0.5 mm long), a cat flea 700–900 within 3–4 weeks. Most species need blood for the development of eggs (anautogeneous). Fertility is reduced if the typical host is not present and if females have fed on other hosts. In some species more than 1 mating is necessary to fertilize all eggs. In the rabbit flea reproduction is regulated by the hormones of the host, i.e., maturation of adults is induced by blood meals from pregnant rabbits or newborn progeny (► [Insects](#), Fig. 2).

Biochemical/Molecular Data

Biochemical investigations focus on the cat flea, e.g., components of the saliva. Other allergens are also considered in mRNA investigations. PCR is used to find pathogen-infected fleas and 18S rDNA sequencing for phylogenetic studies.

Life Cycle

After a temperature-dependent, low-humidity-sensitive (>70 % necessary) embryonic

Fleas, Fig. 3 (a–c)

development of about 5 days, the 1st-▶ instar larvae (1 mm long) hatch. The larvae live in the nest or lair of the host – in houses preferably in carpets – feeding organic material, but mainly

remnants of digested blood and drops of undigested blood, both deposited by the adults during feeding. After two moults within 2–3 weeks, mature larvae spin cocoons from silk

Fleas, Fig. 5 LM of larvae of fleas containing blood excreted by adult fleas (black inclusion)

Fleas, Fig. 6 SEM of a male sand flea (*Tunga penetrans*)

produced by the salivary glands. Dust adheres to the freshly spun silk in which the larva moults to the pupa within 2–3 days, the latter usually completing its development within 1 or 2 weeks. They die if humidity is <45 %. The adult flea remains in the cocoon and can wait long periods of time (6–12 months) until vibrations indicate the presence of a host. (Therefore, after holidays the dog or cat should be the first entering a room.) Adult fleas live several months, sometimes more than a year and can survive long periods of starvation. Under optimal conditions, the whole developmental cycle (egg to egg) lasts about 4 weeks. The majority of species are univoltine. Whereas the majority of fleas irregularly sucks blood and rests near the host or in its fur, the adults of the sand fleas penetrate the skin and develop there, growing to the size of a small pea.

Transmission

Fleas jump from one host to a neighbouring one, the rat and the human flea covering 31 cm in a single jump. Nest-dwelling species do not jump as far. The energy for the jumps cannot be supplied by direct muscle action, but fleas possess a pad of resilin, a protein that can store and release energy like rubber.

Clinical Relevance

Main fleas of medical importance are especially the tropical rat flea ► *Xenopsylla cheopis*, the sand flea *Tunga penetrans*, the cosmopolitan human flea *Pulex irritans* – all possessing no combs – and the cat flea *Ctenocephalides felis*. During the last years especially cat fleas have occurred more often, also on dogs. However, the incidence of the major transmitted disease, plague, has decreased markedly during the last 80 years. Since the rodent hosts cannot be eradicated, outbreaks of plague will regularly occur in many parts of the world, e.g., India and Russia. Fleas may introduce dermatitis in man and animals, too. Recently it was proven that fleas may transmit a wide range of viruses and bacteria by regurgitation of freshly fed blood and via excretion of faeces.

Feeding Behavior and Transmission of Disease

Fleas are attracted to the host by vibrations, warmth, carbon dioxide and shadowing. The natural main host is recognized by specific odours. Fleas are capillary feeders, some species ► *pool feeders*, needing 2–10 min for a blood meal. Pumps transport the blood directly to the midgut in which it is stored and digested. The rupture of erythrocytes is achieved by many series of spines in the ► *proventriculus*. The saliva of fleas causes itching and the resulting scratches secondary bacterial infections. The itching reaction is stronger if the fleas feed on an occasional, not the natural host.

Different flea species of rodents, especially the rat flea *Xenopsylla cheopis*, can transmit classic

Fleas, Fig. 7 Diagrammatic representation of the mating behavior of three flea types, which occur free or partly, respectively, fully attached on the skin of their hosts

Fleas, Table 1 Some common fleas

m male, f female

plague. Usually this occurs if many rats have died of the disease and the infected fleas attack other available hosts, e.g., human. Fleas also transmit ► [tapeworms](#) to cats and filarie to dogs (Dirofilaria, ► [Acanthocheilonema](#)) and ► [murine typhus](#) to man, the latter showing similarities in development and transmission to classic epidemic typhus transmitted by ► [lice](#)

(► [Pediculus](#)). Recent experiments have clearly shown, that fleas may also transmit viruses not only during engorging blood but also via faeces. This was proven for the Calici viruses of cats and Feline leucemia virus of cats. Thus it can be expected that many viruses of a similar stability may be transmitted to animal and human hosts.

Interaction of Vector and Parasite

If the fleas suck blood of a plague-infected host, the causative agent ► [Yersinia pestis](#) is transmitted and multiplies in the lumen of the gut, especially in the foregut, initially resulting in a plug of bacteria which later is partly reduced. The blockage is stronger in the more virulent strains of bacteria which adhere stronger to each other. From the foregut or contaminated mouthparts the bacterium is transmitted to the vertebrate host.

Y. pestis is pathogenic to fleas due to the blockage of the proventriculus by a plug. Since only reduced volumes of blood can be ingested, infected fleas attack hosts more often. If the plug is reduced, more blood can be ingested. The infection not only disturbs blood ingestion, but especially the total blockage reduces longevity.

Diagnosis of Bites

Since disturbed fleas interrupt blood ingestion, usually several neighbouring bites occur.

Control

Information should emphasize the other feeding and infestation paths by larvae and thus the importance of treatment of the house and not only the pet bedding. Pets should permanently wear an anti-flea collar. In regions with foci of sylvatic plague, the rats, ground squirrels, prairie dogs and marmots should be controlled or fed in bait boxes treated with insecticides which then also act in the lair.

Infestations of pets with adult fleas can be reduced with insecticide collars. In infestations of homes, insect growth regulators, which are nearly non-toxic to vertebrates, can be used against larvae, e.g., methoprene, and insecticides against adults (► [Ectoinsecticides](#), ► [Arthropodicidal Drugs](#)).

Fleas: Transmission Experiments of Viruses

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Transmission Experiments with Feline Leukemia Virus

As described in the paper of Vobis et al. (2003), the following results were obtained in an artificial feeding system (artificial dog from FleaData Inc., Freeville, USA), where fleas have the chance to ingest blood from small blood containers via membranes. The whole system was adjusted to keep the blood temperature at 37 °C. In the first feeding, an initial population of 110 fleas was infected with feline leukemia virus (FeLV) through feeding for 24 h with 2 ml blood from a viremic cat (Fig. 1). To verify successful uptake of

viruses, ten fleas and whole feces of this initial population were tested for FeLV RNA. The viral RNA could be detected in both samples, fleas and feces. The FeLV was incorporated by the fleas via blood feeding and was excreted with the feces. The remaining 100 infected fleas were subsequently divided in two populations of 50, where population 1 was fed for 24 h and population 2 for 5 h with 300 µl uninfected blood from a healthy cat. After the defined time, ten fleas and feces of each population were tested for FeLV. Viral RNA could be detected in fleas of both populations as well as in their feces. FeLV RNA was detectable for 5 and 24 h, respectively, after uptake by the flea and feeding with uninfected blood. To investigate whether transmission of FeLV occurred, the remaining blood from transfection 1 and 2 was examined. Viral RNA could be detected in both samples of the previously uninfected blood from a clinically healthy cat. This shows that the cat flea *C. felis* can function as a vector for feline leukemia virus RNA in this in vitro system of an artificial dog. Viral RNA was detectable in the fleas and its feces for up to 24 h. In addition, the fleas successfully transmitted FeLV

Fleas: Transmission Experiments of Viruses, Fig. 1 This diagram summarizes the transmission experiments of FeLV

Fleas: Transmission Experiments of Viruses,

Fig. 2 This figure shows the output of feces of 30 fleas. These feces remained infectious for many weeks, when the fleas had sucked virus containing blood

F

RNA directly from an infected blood sample to an uninfected one. In a third feeding study, the same fleas, feces, and blood samples were examined for FeLV. After this third feeding, viral RNA could not be detected neither in the fleas, their feces, nor in the blood samples. FeLV RNA was detectable in the fleas up to 24 h after feeding. During this time, fleas also excreted viral RNA with their feces. In addition, the fleas were able to transmit FeLV RNA directly from one blood sample to another and functioned therefore as a vector of the virus.

In quantitation measurements (Vobis et al. 2005a, b) using the same artificial dog system as in the first series (Vobis et al. 2003), it was shown that around 70 % of the ingested virus can withstand passage through the intestine with at least an intact nucleocapsid and is excreted and spread into the flea feces and thus into the surroundings (Fig. 2). When comparing the degradation rates of the FeLV in cell culture supernatant, the nucleocapsid seems even more stable in the feces. About 55 % of the initial amount of the viruses could still be detected after 15 days at room temperature. Lower temperatures led to even higher survival rates.

These experiments showed that the viruses were transmitted by sucking (and apparent regurgitation) and that they were definitively surviving for days within the feces.

Transmission Experiments with Feline Calicivirus

In order to find out whether flea feces do not only contain the probably unchanged viruses, in vivo experiments were done using the feline calicivirus (FCV) (Truyen et al. 1999; Mencke et al. 2009). Fleas were inoculated with the viruses in the artificial dog system containing bovine blood free of FCV antibodies but being spiked with FCV to give a final titer of 10^6 TDC₅₀/ml. The flea feces were collected daily for 10 days and incubated at room temperature. When using Crandell-Rees feline kidney (CRFK) cells, it was shown that FCV apparently remained infectious in feces for 8 days. When exposing four specific pathogen-free (SPF) kittens oronasally to the virus-containing feces, all four were successfully infected (two kittens showed clinical symptoms). Four additional SPF kittens were exposed to fleas that had been fed with FCV-spiked bovine blood. One of these kittens was proven to be definitely infected in this way when testing virus isolation from pharyngeal swabs.

The series of experiments clearly shows that fleas may play an important role in the transmission of viruses under certain conditions, either during the blood meal and/or in the case that hosts get in contact with the flea feces. The only very important condition is that the virus is rather stable. However, there are many viruses known to

fulfill these conditions, so that viruses may introduce emerging diseases under these conditions.

Conclusions

This short entry on the potential virus transmission activities of fleas clearly confirmed that fleas are functional vectors for many types of agents of diseases. Their role as vectors of bacteria is clear and well documented in many cases; many undetected transmissions will probably occur daily with those pathogens that introduce rather unspecific symptoms of disease. There is still a need for more examinations. However, the field of the until now apparently completely *underestimated vector capacity* of fleas for the transfer of viruses from one host to the other via blood consumption or by contact of the virus-containing flea feces lets fear for the future. There are huge dangers for outbreaks of viral emerging diseases, especially in crowded camps or under housing conditions with poor hygienic standards, occurrence of masses of potential vectors, etc. Therefore, the prophylaxis rules proposed in the year 1898 by Simond (see special entry in the Encyclopedia) to keep away rats and their fleas from humans are still valid as was confirmed in the reminiscences of his nephew (Simond et al. 1998)!

Flies as Vectors of Fungi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Flies are also known as carriers of fungi that may introduce, e.g., severe diseases due to fungi (*Aspergillus/Penicillium*) (Sales et al. 2002).
Some species are listed below.

Fungi	Disease and symptoms
<i>Aspergillus fumigatus</i>	Aspergillosis: allergic pulmonary disease, aspergilloma
<i>Candida</i> sp.	Candidiasis: dermatitis, intertrigo, intestinal infections
<i>Mucor</i> sp.	Invasive mycosis in the nose and brain
<i>Trichosporon</i> sp.	Invasive skin mycosis (white piedra)
<i>Geotrichum</i> sp.	Fungemia: stages in respiratory excretions
<i>Cladosporium</i> sp.	Skin mycosis, leading to dark scars

Our own findings (Förster et al. 2012) showed that fungi belonging to the genera *Aspergillus* and *Mucor* as well as several members of the Hyphomycetes can be isolated rather often from the surface of the flies caught at all four catching sites (piggens, dog meadow, horse, and cattle stable). Furthermore, flies from the surroundings of the piggens and from the dog meadow also contained either *Mucor* or *Aspergillus* specimens in their intestine. Fungi of the genera *Candida* and *Geotrichum* were found in flies from all catching sites. *Aspergillus fumigatus* was found exclusively at the surface of flies from all catching sites and never in the intestines. Fungi of the genus *Rhizomucor* also occurred exclusively at the surface of flies from the dog meadow and from the cattle barn. Exclusively intestinal

findings were noted in the case of fungi of the genera *Cladosporium* (in flies from horse stables) and *Trichosporon* (in flies from the dog meadow).

It is important, however, that the human pathogenic fungi *Candida albicans* and *Candida tropicalis* in this study only occurred at the dog meadow catching site, which shows how important sanitation measures are around dog meadows inside and outside cities. However, this study is just a glimpse on the situation in nature where apparently enormous risks due to flies exist.

Flies as Vectors of Microorganisms

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In literature flies were described since many years as vectors of agents of diseases in humans and in animals. The following reports in Table 1 are just a glimpse of the high number of papers found.

Own results obtained from flies that were caught close to stables or at dog meadows showed that the variety of bacteria is enormous (Gestmann et al. 2012). Therefore the infection risks due to bacteria on/in flies are surely underestimated (Table 2).

Some commonly found bacteria and their introduced diseases are listed below (Table 3) showing that they are able to initiate epidemics among crowded populations of humans and also in herds of animals kept for human consumption.

However, pathogens on flies do not occur only in and around stables and barns but also at high degrees at downtown sites and recreation places as was shown in studies during 2010 and 2012 at locations of the busy German towns Düsseldorf and Duisburg (Gestmann et al. 2012). These findings are surely transferable to other towns worldwide (Förster et al. 2009).

The agents of disease isolated from flies that had been caught at recreation sites had a less variable spectrum with respect to the different species of bacteria and fungi. The flies at the different catching sites contained the following species and genera:

- 1. Six-lakes region recreation site close to Duisburg (Germany):
 - *Lucilia*: EPEC, *Aspergillus* sp., *Candida* sp.
 - *Sarcophaga*: EPEC, *Aspergillus* sp., *Candida* sp.
- 2. Lake Unterbach (Düsseldorf, Germany):
 - *Sarcophaga*: EPEC, EHEC, *Candida*, *Aspergillus* sp., *Candida* sp.

Flies as Vectors of Microorganisms, Table 3 Bacterial diseases

Agents/species	Disease, symptoms, general transmission
ETEC	Watery diarrhea for 1–9 days owing to attachment to the intestinal wall and release of LT and/or ST toxins; fever; no blood cells in the feces; infections need 10 ⁸ pathogens; transmission via dirty food or drinking water.
EPEC	Watery diarrhea with fever and vomiting; destruction of microvilli by attachment of the bacteria to the intestinal wall, especially in children below 2 years; diarrhea persistent.
EAEC	Up to 33 % of travelers may suffer from this diarrhea, which is due to large bacterial aggregates in the lumen of the intestine. These bacteria produce toxins (EAST 1), petechiae; chronic diarrhea and malabsorption.
EHEC	Gastroenteritis with vomiting and diarrhea; infections are often due to fewer than 100 single pathogens; transmission via drinking water and contact with human or cattle feces; the most common serotype is O157:H7; the recent outbreak was due to O104:H4, which caused bloody diarrhea and in approximately 30 % of cases hemorrhagic uremic syndrome (http://www.rki.de/CLN_109/nn_205760/DE/Content/InfAZ/E/EHEC/EHEC-Abschlussbericht_templateId=raw,property=publicationFile.pdf/EHEC.Abschlussbericht.pdf), with kidney destruction. Bacteria produce Shiga toxins. In many cases diarrhea stops after 4–10 days.
<i>Campylobacter jejuni</i>	This species represents 95 % of the slimy, bloody diarrhea due to <i>Campylobacter</i> bacteria, 400–500 million cases per year, transmission via feces of birds, pigs and cattle, milk, meat, dirty drinking water; 500 bacteria are sufficient to initiate infections; pathogens are found in the stool for 1–3 weeks; incubation period 12 h to 3 days.
<i>Staphylococcus aureus</i>	Watery diarrhea, vomiting, nausea; incubation period 1–18 days after eating contaminated food, wound infections.
<i>Klebsiella pneumoniae</i>	In immunocompromised persons, pneumonia. <i>K. rhinoscleromatis</i> induces nose infections, leading to a bad smelling nose.
<i>Proteus mirabilis</i> , <i>P. vulgaris</i>	They are gram-negative bacteria leading to intestinal diseases and also extraintestinal infections.
<i>Enterococcus</i> sp.	<i>Enterococcus faecalis</i> is a gram-positive bacterium which may act as a nosocomial agent of disease leading to sepsis, endocarditis, peritonitis, urethral infections, cholecystitis, etc.
<i>Providencia rettgeri</i>	These species are gram-negative bacteria which lead to urethral infections and may induce diarrheas, sepsis.
<i>Morganella</i> sp.	These gram-negative bacteria may lead to severe diarrheas, sepsis.
<i>Pseudomonas aeruginosa</i>	This species is a gram-negative bacterium which as a nosocomial agent may induce infections of the urethral channels, wounds, brain, and breathing system; the leading symptom is the production of a greenish-blue mucus.

EAEC enteroaggregative *Escheria coli*, EHEC enterohemorrhagic *Escheria coli*, EPEC enteropathogenic *Escheria coli*, ETEC enterotoxigenic *Escheria coli*

- *Lucilia*: EPEC, EHEC, *Candida*, *Aspergillus* sp.
- *Calliphora*: EPEC, *Aspergillus*, *Candida* sp.
- 3. Park at Castle Eller (Düsseldorf, Germany):
 - *Musca domestica*: EPEC, *Candida*, *Aspergillus*
 - *Sarcophaga*: EPEC, *Candida*, *Aspergillus*
 - *Lucilia*: EPEC, *Candida*, *Aspergillus*
 - *Calliphora*: EPEC, *Candida*, *Aspergillus*
- 4. Downtown Düsseldorf (Germany):
 - *Sarcophaga*: EPEC, *Candida*, *Candidaalbicans*, *Aspergillus*, *Mucor*
 - *Lucilia*: EPEC, *Candida*, *Aspergillus*

– *Calliphora*: EPEC, *Candida*, *Aspergillus*

The total infection rate of flies was very high, whereby the feces showed especially high rates: 60 % of the flies contained EPEC, *Candida* sp. was found in 70 % of the flies, and *Aspergillus* was found in 80 % of the flies.

The results, which were obtained from probes from 2008 until midsummer of 2011, show that both the number of fly species caught and the number of species that are agents of diseases determined were considerably lower than in rural regions close to stables. However, it would be a severe error to believe that there is no chance of an

outbreak of a disease, since all important flies are apparently present and can take up agents of diseases if they are present in open garbage, food, dog feces, bird feces, etc. Thus, attention is always needed to minimize the number of possible breeding sites of flies.

Flies as Vectors of Parasites

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Flies are proven to be important vectors not only of microorganisms such as viruses, bacteria, or fungi but they are also able to transmit parasites. This transmission may occur by contaminated feet. Furthermore, feces of flies often contain numerous parasitic stages such as oocysts of ► *Coccidia* and eggs of ► *trematodes*, ► *tape-worms*, and/or ► *nematodes*. All in all, however, there are rather few intense investigations (Dipeolu 1982; Förster et al. 2007, 2009a, b, 2012; Greenberg 1971, 1973; Szostakowska et al. 2004; Umeche and Mandah 1989). However, the papers of Förster et al. (2009a, b; 2012) and Gestmann et al. (2012) are based on a broad research on flies caught close to pigpens, dog meadows, cattle and horse stables, and chicken farms as well as at downtown recreation sites. All investigated flies showed considerable amounts of specimens of ► *Cryptosporidium* species, ► *Giardia lamblia*, ► *Isospora* species, ► *Balantidium coli*, ► *Ascaris suum*, ► *Metastrongylus apri*, ► *Strongyloides* species, ► *Cystoisospora* species, ► *Toxocara canis*, ► *Parascaris equorum*, ► *Eimeria* species, ► *Trichuris suis*, and ► *Toxocara vitulorum* besides several species of mites.

These findings taken during three seasons underline that there are underestimated risks for humans and animals in rural as well as in down-town locations. This implicates that permanent control measurements are needed throughout the whole year. Otherwise people and their animals live under constant risks to become infected. That this risk is truly existing was shown by experimental transmission experiments (Förster et al. 2012; Gestmann et al. 2012).

To check the efficacy of flies in the uptake of agents of disease, repeated experiments were done and showed similar results, such as with the following test with 120 laboratory-bred *Musca domestica* flies on both sexes. The flies were offered a milk fluid that contained eggs of the nematode species *Ascaris suum* and *Trichuris suis* (Fig. 1). These species are rather common in normal pigpens and occur in even higher numbers in “biological” farms, when compared to normal ones. The intestines of 13 flies (10.8 %) contained eggs of both species, whereas nematode eggs of one or the other species were detected in 46 flies (38.3 %). Eggs of *Ascaris suum* (840 eggs had been included in the food solution) were found in or on 31 flies (25.8 %), and eggs of *Trichuris suis* (200 eggs had been placed in the food solution) were detected in the intestines of 41 flies (34.2 %). The individual load per fly ranged from 1 to 11 eggs in the case of *Ascaris suum* and from 1 to 6 in the case of *Trichuris suis*. 36 eggs were found on the surface of the fly body. Single eggs of both species were detected on the mouthparts,

whereas 29 eggs of *Ascaris suum* occurred on the body as did five eggs of *Trichuris suis*, which apparently had less gluing capacity. This experiment shows how efficient flies might be in their capacity for transmission of parasitic stages if the latter are present inside the substrates visited by flies.

In another experiment laboratory-bred specimens of *Musca domestica* were placed on a fluid containing eggs of the tapeworms *Hymenolepis diminuta* and *Hymenolepis microstoma*, which were cultivated in laboratory rats or mice. From inspection of the surface (after washing) and the intestinal contents, infectious eggs of both species were found again in large numbers (Fig. 2).

Further experiments, where flies were exposed to laboratory-bred larvae of *Angiostrongylus cantonensis*, again showed positive results, since these larvae were found in the intestine as well as on the surface of the flies. Owing to the possible danger of an infection with *Angiostrongylus cantonensis*, only first stage larvae were used in transmission tests and not larvae 3 (which are infectious to humans and which are normally excreted by the intermediate host, i.e., snails) (Fig. 3).

Similar positive results for a potential fly transmission were obtained when different stages (eggs, larva) of the bloodsucking so-called red chicken mite *Dermanyssus* were exposed to flies. Numerous eggs and larvae of the mites were recovered in and on flies exposed to mite cultures.

Flies as Vectors of Parasites, Fig. 1 *Musca domestica*

Flies as Vectors of Parasites, Fig. 2 Light micrograph of a *Hymenolepis* egg

Flies as Vectors of Parasites, Fig. 3 Light micrograph of a larva 1 of *Angiostrongylus cantonensis*

Flies as Vectors of Parasites, Fig. 4 Light micrograph of a fly with a mite on the body

Furthermore, many of the flies caught in the wild were covered with “traveling mites” (Fig. 4). This phenomenon shows how easy it is for pathogenic mite species to be translocated from the wild or stables to human dwellings.

The broad spectrum of parasites found on flies caught in the wild and their rates of infection with different parasites between 0.3 % and 54.5 % show the high potential of flies to act as vectors

of parasites. This is even more understandable considering the individual infection rate (about 0.003 %) of mosquitoes in highly endemic malaria regions. This latter very low infection rate of mosquitoes is, however, sufficient to infect practically all human inhabitants in many regions of the world.

Flight Speed

To attack their hosts parasitic mosquitoes and flies reach a considerable speed: e.g., mosquitoes (3.2 km/h), *Musca* spp. (0.4 km/h), *Calliphora* spp. (11.0 km/h), tabanids (22.4 km/h), Oestridae (*Cephenemyia stimulator* of deer, 40.0 km/h).

Flotation

Method to obtain small-sized cystic parasites from faeces probes (Fig. 1).

Flotation, Fig. 1 Zonation in the tube after centrifugation

FLP

FMRF amide-like peptides (FLPs) play a central role in nematode motor and sensory capabilities. Since they are widely preserved in their sequence in many species of nematodes, they might be candidates for new parasiticides.

This term describes the region of about 11 million square kilometres in Africa where so-called Tsetse flies of the genus *Glossina* occur being able to transmit *Trypanosoma brucei brucei* and related species.

Fly Burden

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Several fly species are common and attack live-stock animals in large numbers. Common counts were shown in [Table 1](#).

Fly Burden, Table 1 Common flies on livestock

Species	Common number of adults per animal
Horn flies (<i>Haematobia</i> species)	200
Nuisance flies (<i>Musca</i> species)	150
Stable flies (<i>Stomoxys calcitrans</i>)	10

Fly Species Distribution in Europe

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

As is shown in the following key words Flies as vectors of microorganisms and Flies as vectors

of parasites, flies may be involved in outbreaks of severe diseases. Depending on their breeding sites they are able to transmit different agents of diseases. Therefore it is worthwhile to know the basics of some important species, some of which are of course different on the four green continents depending on the local temperatures. In Europe the following species are common and important with respect to their potential vectorship of agents of diseases at recreation sites.

Species	Breeding sites
<i>Musca domestica</i> (housefly, typhoid fly)	Eggs and larvae in and on animal feces, even in stables
<i>Musca autumnalis</i> (eye fly)	Eggs and larvae on animal feces outdoors, adults hibernate in buildings
<i>Fannia canicularis</i> (little housefly)	Eggs in feces of chicken and other animals, kitchen slops
<i>Muscina stabulans</i> (false stable fly)	Eggs; larvae often on chicken feces, predacious as well
<i>Stomoxys calcitrans</i> (stable fly; sucks blood every 3 days)	Oviposition on plant material in stables
<i>Haematobia irritans</i> (horn fly)	Eggs and larvae on fresh cow dung
<i>Calliphora vicina</i> , <i>C. vomitoria</i> (blowflies)	Eggs on feces and cadavers
<i>Sarcophaga carnaria</i> (flesh fly)	Eggs and larvae on meat, cadavers, earthworms
<i>Lucilia</i> (syn. <i>Phaenicia</i>) <i>sericata</i> (gold fly)	Eggs in wounds, cadavers, feces

(continued)

Species	Breeding sites
<i>Lucilia caesar</i> (carrion fly)	Eggs and larvae in feces, cadavers
<i>Phaonia errans</i>	Eggs are placed on powdered wood or dry feces
<i>Oestrus ovis</i> (nose botfly)	Larvae are extruded into the nose of sheep and goats
<i>Hypoderma bovis</i> (large skin botfly)	600–800 eggs become attached to hair of cattle
<i>Hypoderma lineatum</i> (small botfly)	5–20 eggs per hair of cattle
<i>Hydrotaea dentipes</i> (carrion fly)	Eggs on feces of humans or animals
<i>Pollenia angustigena</i>	Larvae in earthworms
<i>Pollenia rudis</i>	Larvae in earthworms

Fly-Borne Diseases

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Flies attack animals and humans by licking or even blood-sucking activities during which an exchange of agents of diseases may occur. This field is still poorly investigated, and some examples are listed in Table 1.

Fly-Borne Diseases, Table 1 Examples of fly-borne diseases of ruminants in Europe

Diseases	Pathogens	Main vectors	Other vectors
Pink eye	<i>Moraxella bovis</i> (B)	<i>Musca autumnalis</i>	<i>Musca domestica</i> <i>Stomoxys calcitrans</i>
Mastitis	Various anaerobes (B) <i>Staphylococcus aureus</i> (B)	<i>Hydrotaea irritans</i> <i>Haematobia irritans</i>	?
Bluetongue disease	Bluetongue virus	<i>Culicoides obsoletus</i> <i>Culicoides pulicaris</i>	Tabanids <i>Stomoxys calcitrans</i>
Anaplasmosis	<i>Anaplasma bovis</i> (B)	<i>Ixodes ricinus</i>	<i>Stomoxys calcitrans</i>
Besnoitiosis	<i>Besnoitia besnoiti</i> (P)	Tabanids	<i>Stomoxys calcitrans</i>
Bovine theileriosis	<i>Megatrypanum theileri</i> (P)	Tabanids	<i>Stomoxys calcitrans</i> <i>Ixodes ricinus</i>
Bovine parafilariosis	<i>Parafilaria bovicola</i> (N)	<i>Musca autumnalis</i>	?
Bovine thelaziosis	<i>Thelazia</i> spp. (N)	<i>Musca autumnalis</i>	?
Camel trypanosomiasis	<i>Trypanosoma evansi</i> (P)	Tabanids	<i>Stomoxys calcitrans</i>

B bacterium, N nematode, P protozoan, V virus

FMRF-Amide-Like Peptides (FLP)

These peptides of parasites are targets of new designed antiparasitic drugs (due to their motor and sensory capabilities in signalling).

Focus

Due to the complexity of the synecological systems in which ► [arboviruses](#) circulate, preconditions for the maintenance of the virus cycle are usually fulfilled in limited areas only. These areas are called foci to which the viruses are endemic. ► [Arboviruses/Distribution](#).

Folic Acid

Peter Köhler
Institute for Parasitology, University of Zürich,
Zürich, Switzerland

Folate derivatives are important cellular cofactors in the synthesis of nucleotides and a variety of amino acids as well as for DNA and protein methylations. Like other nonplant eukaryotes, most

parasites lack the biosynthetic folate pathway. An exception is several apicomplexan species that are capable of and dependent on the *de novo* synthesis of folate cofactors from GTP, p-aminobenzoate, and glutamate. This route initially involves the conversion of GTP to dihydroneopterin triphosphate by GTP cyclohydrolase, an enzyme that is considerably different in plasmodia compared to the mammalian orthologue. In apicomplexans, dihydroneopterin triphosphate can then be utilized as a precursor for the biosynthesis of dihydrofolate. Conversion of this product to tetrahydrofolate occurs in both, apicomplexans and their mammalian hosts, by the action of dihydrofolate reductase but the homologous enzyme involved in this reaction can differ remarkably in its properties. In addition to the ability of apicomplexans to synthesize folates *de novo*, these parasites can also salvage folate and various folate derivatives using specific ATP-dependent transport systems. The unique folate biosynthetic features of plasmodia and related protozoans explains the selective toxicity of sulfonamides and folate antagonists against malaria and other apicomplexan-derived diseases and may continue to provide a source for the development of new drugs and novel therapeutic strategies.

Food-Borne Disease Burden Epidemiology Reference Group

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The members of this group are appointed by the WHO and are asked to develop methods and control measurements to minimize parasite-derived losses of human food sources.

Common name of the disease due to infections with *Leishmania guyanensis* (= cutaneous leishmaniasis), also called pian-bois and bosch-yaws.

Formicidae, Ants

Reiner Pospischil
PMP-Biosolutions, Bergheim-Fliesteden,
Germany

Introduction

Ants (Hymenoptera, Formicidae) are one of the most successful insect families worldwide because of their social life and effective defense strategies. They have developed an impressive diversity of species and occupy many ecological niches (Hölldobler and Wilson 1990, 2010). All ant species live in social communities, and most of them play an important beneficial role in natural ecosystems (Klotz et al. 2008). However, a few species have a detrimental impact in urban areas. Some may become passive carriers of pathogens in hospitals (Beatson 1972; Fowler et al. 1993; Moreira et al. 2005; Pospischil 2010), while others cause nuisance by biting or stinging people (Blum and Hermann 1978; Klotz et al. 2008; Schmidt 1986). Some invasive species like the Argentine ant *Linepithema humile* repress other indigenous species which is an unwanted ecological impact.

Formicidae: Development

Ants live in social communities, and the colonies consist of sterile females, which represent the majority of the individuals, eggs, larvae, pupae, and one to many queens depending on the species. The sterile and wingless workers are monomorphic (e.g., *Linepithema humile* and *Lasius* spp.) or polymorphic (e.g., *Atta* spp., *Solenopsis* spp., *Camponotus* spp., and *Pheidole* spp.). Workers who have a particularly broad head and strong mandibles are often referred to as soldiers. Species, which do not have nuptial flights, harbor males in their nests, which do not discard their wings during their life span.

Formicidae: Systematics

The Formicidae belong to the order Hymenoptera. Fossil records indicate that wasps (Vespidae) and ants have the same ancestors. A primitive ant species (*Sphecomyrma freyi*) was found in 80-million-year-old amber from New Jersey (USA). This species has an ant-like petiole and wasplike mandibles. The antennae have characteristics of Vespidae and Formicidae (Hölldobler and Wilson 1990, 2010).

More than 11,500 species have been described worldwide until now which belong to 23 subfamilies and 287 genera (Bolton et al. 2006). Various authors assume that the number may increase in the future to 17,000–20,000 species (Hölldobler and Wilson 1990; Klotz 2004). The European ant species belong to the subfamilies Formicinae, Dolichoderinae, Myrmicinae, and Ponerinae.

Formicidae: Exotic Ants

The introduction and distribution of exotic species often happens with world trade. *Solenopsis invicta* and *Linepithema humile* were transported with logs and lumbers to the south of the USA. *Tetramorium caespitum* and *Myrmica rubra* arrived with dead freight in sailing vessels in the USA from their origin in Europe. Nowadays ant species easily travel between continents with fruits and vegetables, in roots and soil of plants or in flower pots (*Plagiolepis* sp. and *Pheidole* sp.), in dermatiae of leaves, or in cavities inside of bulbs in aircrafts and modern container ships. With container traffic, ant colonies are often not detected in the harbor and arrive at their final destination without being noticed (Boer and Vierbergen 2008; Pospischil 2011).

The introduction of exotic ant species to new countries is not a new problem, but their frequency is increasing with globalization and urbanization (Klotz et al. 2008; Boer and Vierbergen 2008). In 1999 already 147 species of ants have been recorded living in nonnative habitats (McGlynn 1999). Ant species have to

fulfill special requirements to establish in a new country after introduction (Klotz et al. 2008; McGlynn 1999; Tsutsui and Suarez 2003). Workers are often of small size and inconspicuous color. Nuptial flights do not occur and reproduction takes place by budding. Both workers and queens have a high foraging mobility and no specific requirements to the nesting sites. The colonies are polydomous and polygynous. In many species, members of different colonies are not aggressive.

Exotic ants are placed in two categories depending on their behavior after introduction into a new country. Tramp ants live close to people, and they do not expand actively (McGlynn 1999; Klotz et al. 2008). Invasive species spread actively after introduction in urban and rural areas and displace native species (Giraud et al. 2002; Holway et al. 2002; Tsutsui and Suarez 2003).

Linepithema humile, which belongs into the category of highly invasive species, was displaced from its origin in South America worldwide especially in areas with a Mediterranean climate (Holway et al. 2002). Two super colonies of this species are known in southern Europe. The larger colony started from Portugal where it arrived with lumber at ~1,900. From there, it spread along the Atlantic and Mediterranean coast over 6,000 km and reached the north of Italy. The second super colony covers 200 km along the Spanish Mediterranean coast (GIRAUD et al. 2002; REY and Espadaler 2004; SUAREZ et al. 1999). However, the species tolerates low temperatures. Active workers were found in the Netherlands in February 2008 even at temperatures only a few degrees above the freezing point under wood and stone slabs near the foundation of buildings (Pospischil and Brooks 2008). The species displaces the native ant fauna in the vicinity of their nests.

Lasius neglectus has a similar behavior. This invasive species is also polygynous and forms super colonies with high numbers of individuals. The species spread from its unspecified origin in the area of the Black Sea over Hungary in South and Central Europe (Rey and Espadaler 2004; Ugelvig et al. 2008). One *Lasius* colony was

identified in the south of Great Britain 2009 as *L. neglectus*, after it was already present for several decades according to the residents of this location (Boase 2014).

A growing number of ant species with subtropical and tropical origin find shelter in continuously heated buildings (like tropical greenhouses) of temperate latitudes. Examples are *Plagiolepis* sp., *Monomorium pharaonis*, *Tapinoma melanocephalum*, *Hypoponera punctatissima*, *Technomyrmex vitiensis*, and several *Tetramorium* species (Boer and Vierbergen 2008; Czechowski et al. 2002; Pospischil 2011) (Table 1). These species do not tolerate the Central European climate conditions with cold temperatures, and they can only survive in permanently heated buildings with access to high humidity. However, they tolerate cold temperatures during transportation for several weeks depending on humidity.

The white-footed ant *Technomyrmex vitiensis* was introduced into tropical greenhouses at the end of last century and is now the most common ant species in buildings with tropical climate. The species has decentralized colonies over large territories with regular exchange of workers. Inseminated queens are only found in new colonies and

Formicidae, Ants, Table 1 Exotic ant species which are now frequently found in European buildings with constantly high temperature (with special regard to tropical greenhouses)

Subfamily	Scientific name
Formicinae	<i>Plagiolepis</i> sp.
Dolichoderinae	<i>Technomyrmex vitiensis</i> (Mann, 1921)
Dolichoderinae	<i>Tapinoma melanocephalum</i> (Fabricius, 1793)
Myrmicinae	<i>Monomorium pharaonis</i> (Linnaeus, 1758)
Myrmicinae	<i>Tetramorium bicarinatum</i> (Nylander, 1846)
Myrmicinae	<i>Tetramorium insolens</i> (Smith, F., 1861)
Myrmicinae	<i>Cardiocondyla obscurior</i> (Wheeler, W.M., 1929) <i>C. wroughtoni</i> (Forel, 1881)
Ponerinae	<i>Hypoponera punctatissima</i> (Roger, 1859)

Formicidae, Ants, Table 2 Human pathogens found on ants in hospitals (Beatson 1972; Fowler et al. 1993; Faulde 2002; Moreira et al. 2005)

Subfamily	Species	Human pathogen
Myrmicinae	Pharaoh's ant <i>Monomorium pharaonis</i>	<i>Acinetobacter anitratus</i> , <i>B. subtilis</i> , <i>B. cereus</i> , <i>B. pumilus</i> , <i>Clostridium welchii</i> , <i>C. cochlearium</i> , <i>Diplococcus</i> spp., <i>Enterobacter agglomerans</i> , <i>Enterococcus faecalis</i> , <i>E. faecium</i> , <i>Escherichia coli</i> , <i>Gemella haemolysans</i> , <i>Klebsiella pneumoniae pneumoniae</i> , <i>Proteus vulgaris</i> , <i>Pseudomonas aeruginosa</i> , <i>P. fluorescens</i> , <i>Staphylococcus aureus</i> , <i>S. albus</i> , <i>S. lugdunensis</i> , <i>S. epidermidis</i> , <i>Streptococcus faecalis</i> , <i>S. acidominimus</i> , <i>S. pyogenes</i>
Dolichoderinae	Ghost ant <i>Tapinoma melanocephalum</i>	<i>Acinetobacter baumannii</i> , <i>Bacillus</i> spp., <i>Enterobacter faecalis</i> , <i>E. cloacae</i> , <i>G. morbillorum</i> , <i>Klebsiella oxytoca</i> , <i>K. pneumoniae pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>S. epidermidis</i> , <i>S. equorum</i> , <i>S. saprophyticus</i> , <i>S. simulans</i> , <i>S. warneri</i>
Formicinae	Crazy ant <i>Paratrechina longicornis</i>	<i>Bacillus</i> spp., <i>Enterobacter agglomerans</i> , <i>E. cloacae</i> , <i>Gemella haemolysans</i> , <i>G. morbillorum</i> , <i>Klebsiella pneumoniae pneumoniae</i> , <i>Serratia rubidaea</i> , <i>Staphylococcus aureus</i> , <i>S. cohnii</i>

then replaced by the so-called intercastes which can hardly be differentiated from workers (Yamauchi et al. 1991). Transfer of nutrients occurs through trophic eggs rather than trophallaxis. The species tends aphids, and large colonies may interfere with the biological control programs in tropical greenhouses to control aphids (Klotz et al. 2008; Pospischil 2011). Nests of *Cardiocondyla* spp. are well hidden in tiny cavities of plants and active at night. However, they can be annoying because of their painful stings when they are disturbed (Heinze et al. 2006). Small populations of the Ponerinae (*Hypoponera* spp.) which live in the soil and feed on Arthropods are often well hidden and not recognized.

Formicidae: Medical Importance

Synanthropic ant species are mostly only a nuisance in residential buildings. However, in hospitals, they can become dangerous disease carriers, because the foraging workers move over distances of several meter and visit nutrition sources but also waste containers and can penetrate in wound dressings due to their small size.

Formicidae: Transmission of Pathogens

The proliferation of pathogenic bacteria by synanthropic species of ants in hospitals has been described repeatedly (Beatson 1972; Fowler et al. 1993; Faulde 2002; Moreira et al. 2005). In Brazilian hospitals, different ant species were found, of which *Tapinoma melanocephalum* had the highest abundance, followed by *Paratrechina longicornis*, *Monomorium pharaonis*, and *Linepithema humile*. At the collected ants, 40 bacterial species were found, including some of the most important pathogens in hospitals (Ipinza-Regla et al. 1981; Fowler et al. 1993; Moreira et al. 2005). In Europe, only *Monomorium pharaonis* was identified as carrier of human pathogens (Beatson 1972) (Table 2).

Formicidae: Reaction to Stings and Bites

Large species (*Camponotus* spp.) can cause skin injuries through bites, and skin irritation in the area of the wound happens simultaneously through emitted secretions, including formic acid, which are produced in a special gland in the gaster.

The most representative of Myrmicinae that have a functional sting produces proteinaceous toxins, which differ greatly depending on the species (Blum and Hermann 1978). The bites can cause severe and long-lasting skin reactions in sensitive people.

Pogonomyrmex species produce hyaluronidases and phospholipases, which are responsible for the toxic skin reactions to stings (Schmidt 1986). The venom of fire ants (*Solenopsis* spp.) consists of piperidine-containing alkaloids. The sting causes a burning pain and leads to the formation of necrotic pustules. The symptoms can persist for several days to weeks (Baer et al. 1979; Tschinkel 2006; Klotz et al. 2008). Allergic reactions to the venom of *Pachycondyla chinensis* have been reported from Korea (Cho et al. 2002).

Therapy

Streptomycine, Gentamycine.

Free-Living Amoebae (FLA), Introduction

Patrick L. Scheid

Laboratory of Medical Parasitology, Central Institute of the Bundeswehr Medical Service
Koblenz, Koblenz, Germany

General Information

The term “free-living amoebae” (FLA) delimits a rather heterogeneous group of organisms of the obligate parasitic amoeba (e.g., *Entamoeba histolytica*); however, it has no phylogenetic, systematic, and taxonomic relevance (Walochnik and Aspöck 2007). The free-living amoebae, occasionally called “limax amoebae,” live ubiquitous in many humid habitats as components of biocenoses. The trophozoites feed as aerobic, heterotrophic predators on algae, bacteria, cyanobacteria, and fungi, as well as smaller protozoa. They even serve as prey for other microorganisms, such as for amoebophagous fungi. FLA can be found especially in biofilms on various surfaces and substrates. As resistant life stage, a cyst is formed in some species, which largely protects from adverse environmental conditions and therefore provides an enormous tenacity.

Since the FLA feed on bacteria, they affect the microbial community and reinforce the return of nutrients in the soil. By their heterotrophic nutrition, they excrete materials (e.g., minerals), which were bound in the biomass, so that these are available within the environment (Siddiqui and Khan 2012). Biofilms serve the FLA as a basic food and protection, where they adhere as trophozoites on the surfaces. FLA are involved in the biofilm formation and succession as part of this ecological community due to the secretion of metabolic products (Khan and Panjwani 2000). In such a biocenosis, the FLA are in contact with

many other microorganisms. Even after the phagocytosis of microorganisms by FLA, some of these microorganisms are not always digested. There are also microorganisms of human or hygienic relevance hereunder (Scheid 2014).

Such microorganisms are adapted to the intracellular conditions in the amoebae, find suitable growth conditions, if necessary, protection from negative environmental influences, and take advantage of the dispersal in the environment by their amoebic hosts.

Humans are often in contact with the FLA occurring in the environment, under which there are also facultative parasitically living pathogenic species, respective strains (Barker et al. 1992). In particular, when the intensive contact to the people occurs, as it is done through the use of contaminated contact lenses on the cornea, it can cause infections (Grün et al. 2014). The taxonomy of the FLA or other single-celled organisms is subject to a constant change as genetic studies bring new insights concerning phylogeny, which often conflicts with the “classic” phylogeny approach, based mainly on morphological characteristics (Khan 2009). The applied classification (Table 1) includes those FLA that play a role as human parasites and reflects the classification up to the genus level (Page and Siemensma 1991; Mehlhorn and Ruthmann 1992; Khan 2009).

A current FLA alternative FLA phylogeny and nomenclature is presented useful for comparison, which is deduced from information specified by Walochnik and Aspöck (2007) and Adl et al. (2012) (see Table 2). In the phylum Amoebozoa, the authors group in addition to other taxa the Lobosea and the Variosea together with the Mycetozoa. The Hartmannellidae are placed to the Lobosea and the Acanthamoebidae to the Variosea. The Excavata include among others the Heterolobosea with the Vahlkampfiidae, including the genus *Naegleria*. The taxa within the Amoebozoa are extremely heterogeneous, and their genetic divergence is partly considerably greater than between animals and fungi (Walochnik and Aspöck 2007; Scheikl 2009; Adl et al. 2012).

Tellingly, the FLA are classified in this context as “prime examples of problems in phylogeny,

classification, and nomenclature” (Walochnik and Aspöck 2007). As these classifications based on morphological descriptions are not always congruent to the molecular biological findings, therefore often molecular phylogeny and morphological descriptions with their traditional classification exist side by side.

- biocoenoses. These biofilms can be found in natural habitats and artificial water systems in industry, private houses, and also healthcare areas.

The fact that FLA also serve as hosts and vehicles (vectors) for microorganisms within biofilms has an impact on the public health sector, affecting the quality of drinking and bathing water, as well as disinfection measures. In addition to hygienic and medical considerations of such a topic, however, the ecological-microbiological consideration should not be neglected. This applies not only on life in biofilms but also the implications on **evolutionary processes** and **endocytobiont-host interactions**.

The infectious parasitological considerations are naturally the chosen approach of such studies, because in many cases the endocytobionts were discovered during a routine diagnosis in a medical parasitological laboratory. In human medicine, foreign objects (e.g., contact lenses, implants) which are placed in or on humans cause problems with microorganisms in biofilms. Implants pose a high risk of infection from exogenously or hematogenously transmitted pathogens.

The FLA and their endocytobionts play a role while forming biofilms. In tap water, dialysis centers, hospitals, and insufficiently disinfected contact lens containers, potentially human pathogenic microorganisms with a remarkable tenacity can be found.

In the extracellular, fibrous, polymer, exopolysaccharide biofilm matrix of acellular substances, microorganisms are well protected against exogenous influences such as fluctuations in pH, salts, hydraulic loads, toxic heavy metals, antimicrobial agents, and disinfectants (Borde et al. 2013). Therefore, their resistance to adverse environmental conditions or disinfection procedures is significantly increased.

In contrast to suspended and planktonic bacteria which normally can be killed relatively easily with antibiotics and disinfectants, it can be very difficult or impossible to kill off microorganisms in biofilms. This is not only because of the diffusion and reaction barrier but also because of the different physiological state of those microorganisms (particularly bacteria) within biofilms. Therefore, bacteria in biofilms tolerate biocide

Free-Living Amoebae and Their Impact on the Origin of Pathogens and on Evolutionary Processes

General Information

In biofilms, interesting communities which provide a livelihood for many microorganisms can be found on surfaces or boundary layers in

concentrations one to three orders of magnitude higher than in suspended form, and a much longer exposure time is required for their destruction (Flemming 1994).

Some microorganisms contained within cells replicate intracellularly and persist as pathogens which are protected by this niche against the adverse environmental conditions and the immune system of a host. There are numerous examples of such microorganisms which survive, grow, or proliferate within amoebae (Greub and Raoult 2004; Scheid 2014).

In general, it can be stated that endocytobionts within FLA and especially within their cysts are protected against unfavorable environmental conditions and countermeasures to a higher degree compared to their free-floating forms (Greub and Raoult 2004; Wieser and Schubert 2011). Additionally, such adjustments to intracellular life within phagocytosis-active protozoa or cells show the evolutionary potential of these endocytobionts. This led to the term “intracellular biofilms,” whose formation could be observed in vivo and in vitro.

These intracellular biofilms are in principle nothing else than endocytobiont-host relationships. Such intracellular biofilms are responsible in medicine for recurrence and antibiotic resistance. Similar to a biofilm on the surface, an adhesion of microorganisms to a foreign object is often the first step to biofilm generation (Wieser and Schubert 2011).

In particular, if FLA are present in biofilms and there are close ties with many other microorganisms, the odds are for microorganisms to develop human pathogenic properties. The pathogenic potential is therefore not categorically determined, but becomes accessible only after the detailed examination of the amoebae and their biocoenosis. The exact role of different parameters in these relations is certainly still to be discussed, but in terms of intracellular biofilms (endocytobiont-host relationships), there are interactions which have an impact on the virulence and the tenacity of the involved microorganisms and thus also on the FLA.

FLA serve as a kind of test organisms or **“training grounds”** for evolutionary

“experiments” of the endocytobionts to survive intracellularly, for example, in the phagocytes (macrophages) of humans (Molmeret et al. 2005; Steinert et al. 1998; Fritsche et al. 1998).

In the course of the studies of such relationships, it was supposed that FLA play a role in the adaptation (e.g., by *Legionella pneumophila* or *Mycobacterium avium*) to survival in other phagolysosomal cells, such as human macrophages (Cirillo et al. 1997; Steenbergen et al. 2001; Greub and Raoult 2004; Molmeret et al. 2005).

This could mean that the amoebic passage through the amoeba is a prerequisite for the development of virulence factors – and thus for the development of human pathogenic microorganisms. FLA then may play an important role for intracellular microorganisms in the selection and formation of virulence characteristics and of the adaptation of human macrophages (see also Greub and Raoult 2004).

The uptake into both phagocytosis-active “cell lines” (macrophages and amoebic trophozoites), the replication sites, the release of microorganisms (often by lysis, degradation, or rupture), and the evasion mechanisms of phagocytosis (e.g., avoiding phagosome-lysosome fusion) are well studied for some endocytobionts and are very similar in comparison. Even the lysis of the hosts (macrophages or FLA) after proliferation is caused by exactly the same mechanisms (Greub and Raoult 2004).

Therefore, it is obvious that an adaptation to life in a eukaryotic host for such microorganisms is in evolutionary terms a kind of preadaptation for the ability to infest Metazoa and thus also humans – i.e., as human pathogenic microorganisms. Virulence and resistance to antibiotics are often associated in bacteria (Cirillo et al. 1997; Steenbergen et al. 2001). Therefore, FLA can therefore be viewed as evolutionary trigger or incubators.

In general, such relationships are important “sources” of evolutionary development.

Such FLA which strike up stable relations with endocytobionts often receive substantial selective advantages in comparison with FLA without such relations. Adapted endocytobiont-host

relationships can lead to a stable symbiosis (better endocytobiosis), while accidental intracellular relationships are often negative for one of the partners (see section “Introduction of a Generic Term for Intracellularly Existing Organisms Within FLA” within the entry “► [Free-Living Amoebae as Vectors of Human Pathogens](#)”).

FLA from the latter relationships are killed if they uptake those endocytobionts, thus consequently affecting the entire host amoeba population. Such endocytobionts should be classified as “endoparasitic” organisms following the definition properly. The amoebae can be classified as “opportunity hosts.”

The possibility of adapting to human cells by a protozoan passage is a way to explain the human pathogenicity of microorganisms in itself. The interaction of microorganisms with host amoebae leads to the formation of mechanisms that in turn are found later in the human host as pathogenic mechanisms.

To sum up, the uptake and inclusion of other organisms over a long period without any damage to the host organism can lead to changes (also at the genome level) in the two microorganisms involved. For the host, this includes the possibility to take advantage of new metabolic pathways which were not possible before the relationship arises. These newly developed organisms have significantly different ecological properties which could prove to be an evolutionary driving force. Conclusively FLA-endocytobiont relationships are of relevance for the origin of pathogens and make an impact on evolutionary processes.

Free-Living Amoebae as Human Pathogens: (Genus) *Acanthamoeba*

Patrick L. Scheid

Laboratory of Medical Parasitology, Central Institute of the Bundeswehr Medical Service Koblenz, Koblenz, Germany

Introduction

Acanthamoebae are probably the most common, most known, and most widely distributed facultatively parasitic, free-living (naked) amoebae.

Infectious Agent

Infectious agents of the acanthamoebiasis are obligate parasitic free-living amoebae of the genus *Acanthamoeba*. *Acanthamoebae* are ubiquitarily distributed worldwide within natural and artificial habitats/substrates. In the environment, they survive in many different substrates and biofilms, where they belong to the normal flora and feed on bacteria and fungi in your

environment. Certain species (better: strains) are described as infectious agents of disease symptoms. Among these species, there are pathogenic and not or less pathogenic strains. The acanthamoebae belong to the Sarcomastigophora (Rhizopoda), phylum Sarcodina, class Lobosea, subclass Gymnamoebia, order Amoebida (Centramoebida, Acanthopodida), family Acanthamoebidae, and genus *Acanthamoeba*.

Life Cycle

The motile, multiplying and metabolically active, mononuclear stage is called trophozoite (15–55 µm). This trophozoite engulfs bacteria, yeasts, and algae from the environment via phagocytosis. After phagocytosis, the lysis of the food particles in the phagosomes starts due to the formation of the phagolysosome (phagosome-lysosome fusion). These lysosomes are organelles which are surrounded by a biomembrane and contain digestive enzymes.

Pore-forming polypeptides play a role in the phagocytosis of microorganisms but also when targeting eukaryotic cells, being in contact with the amoebal trophozoites. These mechanisms are well described similar to the amoebapore from *Entamoeba histolytica* (Leippe and Herbst 2004).

The trophozoites encyst in case their environment is unfavorable due to food shortages, drought, or accumulation of metabolic end products. The cysts are resistant to drought, cold, heat, and various “antimicrobial” means (Ma et al. 1990). Due to this high tenacity, they remain infectious months or years and can survive even in dust. Often, the cyst morphology is used to divide the acanthamoebae morphologically in three groups (groups I, II, and III). In addition to these divisions based on morphological criteria, the acanthamoebae are divided by molecular means into 18 sequence types (genotypes) (T1–T18). Almost all keratitis pathogens include sequence type T4. Also for GAE cases, T4 is the prevailing sequence type, but other genotypes were described in associations with clinical relevance as well (Grün et al. 2014).

Clinical Relevance

Acanthamoebae access humans via respiratory tract, wounds, lesions, or skin ulcerations. Wearing contact lenses and microlesions in the cornea are regarded as predisposing factors for the emergence of an *Acanthamoeba* keratitis. The acanthamoebae reach the contact lens storage containers via tap water or air. Even within these containers, they are not eliminated by many disinfectants, but they can proliferate and eventually reach the eye with the contaminated contact lenses.

A whole spectrum of clinical symptoms is caused by acanthamoebae (Khan 2009).

Granulomatous Amoebic Encephalitis (GAE)

Some strains of the genus *Acanthamoeba* are the etiologic agents of the granulomatous amoebal (meningo-) encephalitis (GAE). This CNS amoebiasis differs clinically and morphologically basically from the “primary amoebic meningoencephalitis” (PAM), which is caused by *Naegleria fowleri*. The GAE can be subacute to chronic. Symptoms of GAE are headache, neck stiffness, seizures, memory disorders, and hemipareses. The GAE is characterized by granular, focal brain lesions as opposed to an infection with naegleriae. Brain necrosis and edema are the result. Acanthamoebae can build cysts in the brain tissue and cerebrospinal fluid as opposed to naegleriae. Strains of the species of *Acanthamoeba castellanii*, *A. royreba*, *A. culbertsoni*, *A. polyphaga*, *A. griffini*, *A. astronyxis*, *A. lenticulata*, *A. divionensis*, *A. healy*, *A. jacobsi*, *A. mauritaniensis*, *A. palestinensis*, *A. terricola*, and *A. rhysodes* are described as potential causative agents of GAE. Since usually only patients with weakened immune system or chronic diseases are affected by the GAE, acanthamoebae are considered opportunists. The settlement at the nasal mucosa is discussed as invasion origin. Via the olfactory neural epithelium, they reach the brain. Inhalation of cysts or the penetration through skin lesions is usually described as initial entry routes for the trophozoites. They forward hematogenously to the central nervous system. There they can lyse the brain cells, engulf, and induce apoptosis. The predominant

genotype in the GAE is T4, whereas also the genotypes T1, T10, and T12 are described as GAE inducing. Nonspecific symptoms include fever, headache, nausea, vomiting, lethargy, neck stiffness, and clouding of consciousness until coma.

***Acanthamoeba* keratitis**

The *Acanthamoeba* keratitis is not necessarily associated with an immune suppression, but rather with a trauma and exposure to contaminated water or (soft) contact lenses (Scheid et al. 2008). By improper use or inadequate disinfection of contact lenses, acanthamoebae can penetrate the cornea and cause a very dangerous infection of the eye. User of soft contact lenses has an increased risk of this disease as well for other infectious eye diseases. The acanthamoebae feed in this case from bacteria within the biofilm of the contact lens storage cases.

Several species (better strains) of the genus *Acanthamoeba* have been described already in the contact lens-related keratitis, such as *Acanthamoeba castellanii*, *A. polyphaga*, *A. hachetti*, *A. culbertsoni*, *A. rhyodes*, *A. griffini*, *A. lugdunensis*, *A. quina*, *A. lenticulata*, and *A. royreba*. Prerequisite for an invasion of the cornea is usually a damage to the epithelium leading to small lesions. The amoebae enter through these lesions in the corneal tissue. There, the trophozoites cause an acute keratitis, which develops into a chronic progressive ulcerative keratitis. Nonspecific symptoms are redness, pain, tearing, and light sensitivity. The disease is furthermore characterized by severe eye pain, impairment of vision, a foreign body sensation in the eye, and a frequently occurring whitish flammable ring filtrate. Conjunctivitis, uveitis, and scleritis are also caused by this amoebal infection of the eye, which can lead to corneal perforation and a complete vision loss. The most keratitis-inducing acanthamoebae fall into sequence type 4, but also the genotypes of T2, T3, T5, T6, T11, T13 and T15 were already proven in *Acanthamoeba*-associated keratitis cases (Grün et al. 2014).

Skin Infections Caused by *Acanthamoeba* spp.

The rare cutaneous acanthamoebiasis is a granulomatous, inflammatory skin disease with skin

lesions, ulcers, and erythematous sores. Starting from this inflammatory skin reaction, a spread to the lungs via blood flow to other organs of the body (often the central nervous system/brain) is possible.

Disseminated Infections: *Acanthamoeba* Within the Lungs (FLA Pneumonia)

Since the 1970s, it is known that the acanthamoebae intruded within human lungs can be not only pathogenic but also allergic (e.g., "Pontiac fever," "humidifier" fever, hypersensitivity pneumonia) (Marciano-Cabral and Cabral 2003).

Free-Living Amoebae as Human Pathogens: *Balamuthia mandrillaris*

Patrick L. Scheid

Laboratory of Medical Parasitology, Central Institute of the Bundeswehr Medical Service
Koblenz, Koblenz, Germany

Introduction

Balamuthia mandrillaris has been found in the brain of an 8-month-old pregnant mandrill, who

died in the San Diego Zoo (Wildlife Park) developing a meningoencephalitis. The first publication about the causative agent was made by Visvesvara et al. (1993).

General Information

Balamuthia mandrillaris is related to the *Acanthamoeba*.

Classification

Phylum, Sarcomastigophora (Rhizopoda); subphylum, Sarcodina; class, Lobosea; order, Amoebida (Centramoebida, Acanthopodida); family, Acanthamoebidae; genus, *Balamuthia* (see also ► [Free-Living Amoebae \(FLA\), Introduction](#)).

As in many other free-living, heterotrophic amoebae, trophozoites and cysts are the predominant stages within the life cycle. The trophozoites are approximately 10–60 µm in size and multiply by division. The cysts are irregularly round with a thick wall and a diameter of approx. 6–30 µm. They are formed to survive unfavorable environmental conditions.

The ecological niche of *Balamuthia mandrillaris* is still relatively unknown. Only a few isolations from the environment are described, although currently it is estimated that *Balamuthia mandrillaris* occurs ubiquitously in freshwater, in moist soil, and even in dust. Balamuthiasis cases are described from all over the world. Most cases are diagnosed in the United States, particularly among the Latin American population. *Balamuthia mandrillaris* could be detected during the “environment” investigation in a potting soil from a flower stick in the child’s room when investigating the death of a 3-year-old child in California. *Balamuthia mandrillaris* was found also in a mandrill, in a gorilla, in an orangutan, in dogs, in horses, and in sheep. *Balamuthia mandrillaris* seems to be more common in warm climates where they feed from other FLA, possibly also from other protozoa.

Clinical Relevance

The trophozoites of *Balamuthia mandrillaris* spread after the infection through the respiratory tract or skin injury hematogenous or via the nervus olfactorius (Kiderlen and Laube 2004). Recently also *Balamuthia* infections after organ transplantations are described. These are the only human-to-human transmissions so far. The incubation period is weeks to months, even 2 years are described. Usually immune-compromised but also immune-competent people get infected. Immune-compromised persons (such as HIV) or persons after treatment with immunosuppressive and cytotoxic drugs belong to the risk groups for a GAE.

Many amoebae infiltrate the brain and lead to an amoebic perivascularitis with thrombosis of the capillaries and microinfarcts of the brain substance. The clinical picture of the granulomatous amoebic encephalitis by *Balamuthia mandrillaris* (GAE or also BAE) is characterized by headache and neck stiffness. The course can be insidious and subacute to chronic. Confusion, memory problems, personality change, lethargy, vomiting, seizures, and fever are other manifestations of GAE, which is diagnosed most frequently post-mortem. The *Balamuthia* infection is also known as granulomatous *Balamuthia* encephalitis and is fatal in most cases. Approximately 98 % of the cases (discovered) with Balamuthiasis are fatal. Only a few cases have been diagnosed premortem and could be treated successfully. Apart from the brain, also other organs such as the skin, lungs, kidneys, and the adrenal glands can be infested.

Free-Living Amoebae as Human Pathogens: *Naegleria fowleri*

Patrick L. Scheid

Laboratory of Medical Parasitology, Central
Institute of the Bundeswehr Medical Service
Koblenz, Koblenz, Germany

Introduction

To distinguish naegleriasis from the encephalitis induced by *Entamoeba histolytica* or other free-living amoebae, the term “primary amoebic meningoencephalitis” was chosen. Naegleriasis is basically a rare disease; however, case reports gain regular attention, such as, for example, the death of children or young people, e.g., from the United States, after they were infected typically while swimming in lakes in the summer months.

Infectious Agent

The genus *Naegleria* includes more than 30 species which have been isolated from environmental samples (so far). The only human pathogen *Naegleria* species is the thermophile *Naegleria fowleri*.

Classification (see also FLA introduction chapter)

Kingdom: Eukaryota

System: Protozoa (collective term)

Phylum: Heterolobosa

Class: Schizopyrenidea

Order: Schizopyrenida

Family: Vahlkampfiidae

Genus: *Naegleria*

Species: *Naegleria fowleri*

Naegleria can be found as substrate settlers within moist habitats – mainly in freshwater lakes and ponds (Martinez and Visvesvara 1997), in moist soil, warm/hot springs, etc. Thermophile species like *Naegleria fowleri* could be isolated from artificially heated waters

such as (around) swimming pools and swimming ponds, industrial effluents, drinking water supply lines, or watercourses in the area of introduction of heated industrial wastewater (cooling water from power plants) (De Jonckheere and Van de Voorde 1977). Cerva and Novak described 16 deaths from *Naegleria* infection in children in the Czech Republic in the years 1962–1965 following a swimming pool visit (Cerva and Novak 1968).

Life Cycle

The motile, multiplying, and metabolically active, mononuclear stage is called trophozoite.

The trophozoites of *Naegleria fowleri* are the infective stages. Their size is 7–35 µm. In the amoeboid stage, the promitotic cell division occurs. The trophozoites are able to form cysts under unfavorable environmental conditions. The double-walled cysts are round oval, 7–19 µm in size. They are surrounded by a thick endocyst and a thinner ectocyst. Striking are the pores, which play a role in the excystment process. In addition to the trophozoites and cyst stages is the genus *Naegleria* is able to form a two-flagellate stage. This stage is formed in unfavorable environmental conditions and allows a faster relocation, e.g., to forage.

As amoebal flagellates, they don't uptake any food however and do not proliferate. These pear-shaped flagellates are 15–20 µm in size. *Naegleria fowleri* proliferates more particularly well at temperatures around 30 °C. A mouse pathogenicity, but no human pathogenicity, was demonstrated for *Naegleria australiensis* and *Naegleria italica*. The species *Naegleria gruberi*, isolated frequently from environmental samples, is also not a human pathogen.

Clinical Relevance

So far, only *Naegleria fowleri* is known in humans as infectious agent of the primary amoebic meningoencephalitis (PAM) in humans. Naegleriasis is a diffuse meningoencephalitis; the cerebral

hemispheres are swollen and edematous. The trophozoites cause an inflammation as well as a massive tissue destruction in the brain. The cytopathogenic mechanisms by *Naegleria fowleri* include phagocytosis (trogocytosis) as well as the secretion of cytolytic substances (proteinases). Also pore-forming proteins have been described (Leippe and Herbst 2004). These processes – similar to *Entamoeba histolytica* – are referred to as “nibbling.” These mechanisms lead to extensive tissue damage and numerous local necroses and bleeding. Many focal, superficial hemorrhages can be found within the cortex. The cerebrospinal fluid appears cloudy and hemorrhagic, and the cell number as well as the CSF pressure are elevated when the disease is progressive. Symptoms occur suddenly and include severe headache, confusion, lethargy, somnolence, nausea, vomiting, fever, stiff neck, and inflammation of the respiratory tract. After a critical period with ataxia, convulsions, and coma, the patient often dies within 1–14 days (Martinez and Visvesvara 1997).

The naegleriasis is provoked exclusively by trophozoites, which reach the brain via nasal mucosa when bathing or diving (generally in the leisure water contact) in contaminated waters. In contrast to acanthamoebiasis, the immune status of the affected person does not really matter when in contact to *Naegleria fowleri*. Mostly children and young people are affected during the summer months in warm lakes or ponds. The trophozoites penetrate the nasal mucosa and reach the frontal brain via the olfactory nerves, where they continue to spread and reproduce, without producing cysts (in contrast to the *Acanthamoebae*).

The most common sources for PAM infections are artificial, contaminated, warm water (swimming pools) or warm, standing water such as ponds. The first symptoms occur after a very short incubation period of 2–7 days. The course is often fulminant; the death is about 72 h after the onset of the first symptoms of primary amoebic meningoencephalitis.

The recreational behavior in warm surface water is probably the reason for the increasing numbers of infections with *Naegleria fowleri*. Due to their swimming and bathing behavior,

especially children are affected from a PAM infection. Basically only the avoidance of contact with temperatured, contaminated waters (surface) helps as a preventive measure.

Free-Living Amoebae as Human Pathogens: Others Associated with Pathogenicity in Humans

Patrick L. Scheid

Laboratory of Medical Parasitology, Central Institute of the Bundeswehr Medical Service
Koblenz, Koblenz, Germany

General Information

The *Sappinia* have been identified as etiological agent of an ameba-associated encephalitis (Gelman et al. 2003). The formerly healthy patient survived the infection. Incubation time and source of infection remained unknown. The clinical picture is characterized by vomiting, headache, photophobia, and discomfort to unconsciousness. *Sappinia* species (*Sappinia pedata* and *Sappinia diploidea*) are widespread throughout the world. Amoebic encephalitis associated with *Sappinia* (SAE) was first thought to be proved by *Sappinia diploidea*; molecular biological studies revealed that *Sappinia pedata* was identified as the infectious agent (Qvarnstrom et al. 2009). Therefore, despite this first publication, it remains unclear

whether *Sappinia diploidea* can cause an infection in humans and animals at all.

Also *Hartmannella* sp. has been demonstrated in keratitis cases. It remains open whether Hartmannellae may play a role in the pathogenesis or whether they were discovered only as contaminants (Tsvetkova et al. 2004). The same applies to *Vahlkampffia*, which were found together with Hartmannellae in a keratitis case of a contact lens wearer (Aitken et al. 1996).

Paravahlkampffia francinae n. sp., a recently described amebal species within the genus *Paravahlkampffia*, was isolated from the cerebrospinal fluid of a patient with PAM-like symptoms, which usually are caused by *Naegleria fowleri* (Visvesvara et al. 2009). The patient survived and recovered from all symptoms. The authors concluded that some of the encephalitis infections previously attributed to *Naegleria fowleri* might be caused by *Paravahlkampffia francinae* n. sp. (Visvesvara et al. 2009).

The only case with *Dictyostelium polycephalum*, a social amoeba, associated to a human keratitis is described in 2010 in India. The species *Dictyostelium* belongs to the Mycetozoa, the slime molds (Unikonta, Amoebozoa, Stelamoeba). During their growth and reproduction, they show single-celled “free-living amoebae,” which primarily feed on bacteria. They join them together to a multicellular association when a food shortage happens and form subsequently fruiting bodies (Reddy et al. 2010). As of this single-celled stage, this keratitis case is presented in the present overview of other free-living amoebae as human pathogens.

Free-Living Amoebae as Vectors of Human Pathogens

Patrick L. Scheid

Laboratory of Medical Parasitology, Central Institute of the Bundeswehr Medical Service
Koblenz, Koblenz, Germany

Introduction of a Generic Term for Organisms Existing Intracellularly Within FLA

Those microorganisms adapted to an intracellular life within FLA benefit from the suitable growth conditions, the protection against adverse environmental conditions and may benefit from, distribution with the help of their hosts or vehicles. This phenomenon has led to the term “FLA as the Trojan horse of the microbial world” (Barker et al. 1992; Khan 2009).

Numerous attempts to define the relationships between the intracellular microorganisms and their hosts, the FLA, have not yet been adequate. Terms such as symbionts, endosymbionts, or endobionts are not uniquely defined and differ between language areas. Proposed terms such as “ARB” (amoeba-resistant bacteria) do not include in their scope such organisms as intracellular fungi, viruses, or other eukaryotes (Greub and Raoult 2004). Therefore, we propose to name these intracellular microorganisms, being

associated with FLA, as “endocytobionts” (e.g., Scheid et al. 2008, 2010). It is expedient to call these organisms “endocytobionts” at least during the initial steps of the studies. Hence, we do not need to go into potential characteristics of these relationships such as parasitism, phoresy, zoochory, or mutualism, at an early stage of the study. These relationships can also be variable depending on the temperature (*Legionella* and *Acanthamoeba* as an example) or other environmental conditions. Endocytobionts are defined as more or less autarkic phenomena, being divergent from the host genome. It is therefore of minor relevance whether they emerge facultatively or obligatorily (Kleinig and Sitte 1984). Endocytobiology deals with the studies and the classification of (intracellular) endocytobiosis. In contrast, symbiosis is defined as the coexistence for mutual benefit of adapted organisms (symbionts) of different species. There exist many examples of symbiosis, for example, the relationship between fungi and algae (lichens). For most of the relationships between FLA and intracellularly replicating organisms, the term “symbiosis” does not apply at all, because in most of the cases the amoebae are harmed by some means. In 1883, Schimper created the endosymbiont theory (Schimper 1883). Basically this theory states that autoreduplicative plastids and mitochondria are derived from ancestral protozoa. These protozoa were incorporated as cytosymbionts within the cell at early stages of evolution. Gradually they were domesticated as organelles. Cyanobacteria are seen therefore as an ancestral part of the plastids, while mitochondria descend from Proteobacteria. An ancestral eukaryotic cell phagocytized these bacteria without being able to lyse them or use them as food. Subsequently they developed into endosymbionts (Schwemmler et al. 1984). Such an evolutionary process shows the adaption of endocytobionts to their hosts (Greub and Raoult 2004). In particular, parasites played an important role in the evolutionary process through the “arms race” with their hosts. Thus, endosymbiosis could have contributed to the complexity of parasitic protozoa early in the history of evolution. Certain dinoflagellates are known to incorporate phototrophic and

eukaryotic protozoa as endocytobionts, leading to permanent endocytobiosis. As some of these endocytobionts within FLA are of human pathogenic relevance, the FLA therefore serve as hosts, vehicles, or vectors in addition to their role as potential human pathogens (Scheid 2007; Scheid et al. 2008). As we do not see the need to extend the term “symbiont” artificially, the term “endocytobiont” is a suitable term to outline these intracellularly surviving microorganisms.

Host-Endocytobiont Relationships in Free-Living Amoebae (FLA)

FLA usually uptake other microorganisms as predators by phagocytosis (and food cup building) and lyse them subsequently intracellularly in food vacuoles (phagosomes). Some of these potential prey organisms resist or escape their fate that awaits them by the exposure to oxygen radicals, the acidic environment, and the lysosomal enzymes in the phagosomes. In 1956 an intracellular bacterium, *Sarcobium lyticum* (later known as *Legionella lytica*), has been described in an *Acanthamoeba* strain isolated from soil, which showed not to be culturable extracellularly in subsequent investigations and therefore was proved obligate intracellularly (Drozanski 1956; 1991). The most “famous” relationship in this sense is the intracellular proliferation of *Legionella* bacteria in *acanthamoebae*. Rowbotham has carried out cocultivation assays of *acanthamoebae* and legionellae in 1980 successfully. These legionellae were located intracellularly and proliferated at 35 °C in the FLA. FLA serve therefore as hosts or reservoirs and vehicles of *Legionella* and have also a protective function (Rowbotham 1980). Similar findings count for Chlamydiae, which are important human obligate intracellular, pathogenic microorganisms as well (Michel et al. 2004, 2005). Three *Chlamydia* species are known to cause various diseases in humans (so far).

In addition to bacteria, also viruses, fungi, and protozoa were found intracellularly, and a proliferation in the FLA or a distribution through these FLA at least was demonstrated (for overview see Greub and Raoult 2004; Scheid 2014). During the

last 10 years, publications on the association of viruses with FLA increased. Some of these viruses were called giant viruses mainly due to their size and gene repertoire.

A selection of some microorganisms that use FLA as hosts or vehicle is shown in Table 1, together with their host amoebae and some of their citations. Because it makes a significant qualitative difference, whether the endocytobionts could be isolated from real specimens in situ (e.g., in the context of environmental studies or from patient specimens) or within the framework of cocultivation assays (under laboratory conditions), the real examples resulting from the “environment” are highlighted in gray.

The competence of the FLA as distributors, hosts, or vehicles for endocytobionts was demonstrated in the majority of cases initially in laboratory examinations (in vitro). Host amoebae have their main significance as hosts and vehicles of the intracellular organisms for their distribution or for their proliferation. Newly discovered endocytobionts, which are found in close sympatric association with FLA, are added to this list. *Acanthamoebae* are the predominant FLA as hosts of those endocytobionts within FLA.

Frenkel, Jakob Karl (1921–2013)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Born in Darmstadt (Germany), deceased in Santa Fe (USA) – he was one of the outstanding American medical parasitologists with a broad international reputation. He studied at UCLA at Berkeley and San Francisco School of Medicine, started as a researcher at the Rocky Mountain Laboratory at Hamilton, stayed at the NIH (Bethesda), and was full Professor at the Universities of Kansas City, Kansas (1956–1996), and later in Albuquerque (New Mexico) (Fig. 1).

His name is connected with breakthrough discoveries of several severe human and animal diseases such as *Pneumocystis jiroveci*, *Toxoplasma gondii*, *Besnoitia* sp., *Hammondia* species, as well as *Sarcocystis* species. His close cooperations with American and German colleagues enlightened many fields in protozoan diseases, which had been controversially discussed before by the international scientific community. Therefore it is not astonishing that he was awarded by several national and international honors and asked from many countries to teach their medical, veterinarian, and biological parasitologists. He published more than 300 articles and a book. From the German government he received the highest German scientific honor, when he was awarded for 1 year with the Alexander von Humboldt

Frenkel, Jakob Karl (1921–2013), Fig. 1 Jack Frenkel in his 1970s

scholarship. Furthermore he received a long list of awards of American universities, since he was not only a parasitologist but studied a long list of diseases such as pneumocystosis, cytomegaloviruses, leptospirosis, legionnaire's diseases, and Addison's disease as a pathologist.

Frenkelia

Genus of tissue-cyst-forming ► [Coccidia](#), named in honor of Prof. Jack Frenkel, Kansas City, USA.

Fülleborn, Friedrich Georg Hans (1866–1933)

German physician (Fig. 1) and 1930–1933 director of the Hamburg Tropical Institute, important

Fülleborn, Friedrich Georg Hans (1866–1933), Fig. 1 Professor Dr. Friedrich Fülleborn just prior to his death

reports on ► [filariidae](#), leader of Filaria expedition (1908/1909).

Fumagillin

Insecticide to be used against *Varroa* mites.

Fur Mite

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trivial name for ► [Cheyletiella](#) mites.

Furazolidone

Drug used for treatment of giardiasis and *Blastocystis* infections. ► [Antidiarrhoeal](#) and [Antitrichomoniasis Drugs](#).

Furcocercariae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *furca* = fork with two stings; Greek: *kerkos* = tail.

This term describes larval stages of the digenetic trematode family ► [Cyathocotylidae](#). Their propelling “tail” ends in a structure looking like a

F

Furcocercariae, Fig. 1 Scanning electron micrograph of the furcotailed cercaria of *Schistosoma mansoni*

fork with two stings (Fig. 1). These cercariae enter their host by penetration of their anterior portion = young worm, while the furcous tail remains outside.

G

Gadflies

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trivial name for members of the Tabanidae.

GAE

Granulomatous amoebic ► [encephalitis](#) of man due to infection with ► [opportunistic agents](#), amoeba of the genera *Acanthamoeba* and *Balamuthia*, which also may penetrate and thus destroy the cornea of the eyes.

Gaigeria pachyscelis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Hook worm of the nematode family
Ancylostomatidae of sheep and goats in Africa,

South America, and Asia. For life cycle see ► [Ancylostoma](#). This species was described, e.g., in African sheep parasitizing in the small intestine and being sensitive against fenbendazole.

Galactogenic Transmission

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Transmission of parasites through the milk of the mother of a baby or a puppy (e.g., larvae 3 of ► [Toxocara](#) worms or relatives, larvae of ► [Schistosoma](#) species, ► [Toxoplasma gondii](#) trophozoites.

Galenus, Claudius (129–199)

Greek-Roman physician, besides Hippocrates the most famous physician of the Antique.

single microtubules at the posterior end. At the top of the sperm a pointed fortified acrosome is formed (with a species-specific structure). The female gametes (oocytes) are spherical or ovoid and often rather large in comparison to the female insect.

Galleria mellonella

Species of the butterfly group, a moth, that parasitizes inside stocks of bees.

Gametes: Protozoa

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

GALT

Gut Associated Lymphoid Tissue, Immune System.

Formation of sexual stages in ► [Protozoa](#) is known for sporozoans including the ► [piroplasms](#), Ciliata, ► [Opalinata](#), ► [Hypermastigida](#) (Fig. 7), and recently for trypanosomes (Fig. 6), but definite gametes are not always present (cf. ► [Platyhelminthes](#)/Gametogenesis, ► [Nematodes](#)/Gametogenesis). In the other groups, the formation and fusion of gametes may be hidden. This may occur especially in those cases where the number of gametes is low and where no clear differences between the fusing gametic partners are recognizable. Such ► [isogametes](#) that look similar light microscopically, are found in the Opalinata, some ► [gregarines](#), *piroplasms*, and apparently in trypanosomes, where a true fusion of ► [epimastigotes](#) is postulated to occur just before entering the salivary glands. In some gregarines, ► [anisogametes](#) are described where both types of gamonts undergo divisions. In classic ► [Coccidia](#) (e.g., ► [Eimeria](#) spp., ► [Isospora](#) spp.), tissue-cyst-forming coccidians (► [Sarcocystis](#) spp., ► [Toxoplasma gondii](#), etc.), classic ► [Haemosporidia](#) (► [Plasmodium](#) spp., *Leucocytozoon* spp., etc.), and adeleideans (e.g., *Klossia*), micro- and macrogametes are formed (Figs. 1 and 2). The whole process is called ► [oogamy](#), since here only the microgamont is divided, whereas the macrogamont develops into

Gambusia

Genus of fish to be placed into ponds to control ► [mosquitoes](#) by eating their larvae.

Gametes: Insects

The male gametes (sperms) of insects are in most cases flagellated with a species-specific size ranging from 20 µm until often 10 mm. The sperms include a nucleus, mitochondria, and an axoneme, which contains microtubules either in a 9 × 2 pattern or in a 9 + 9 + 2 pattern, terminates in

Gametes: Protozoa,

Fig. 1 (a–f) Diagrammatic representation of the formation of male (micro-) gametes of eimerian Coccidia (*E. maxima*) along the surface of microgamonts. Other species have only two free ► **flagella**. *B* basal body, *CL* ► **centriole**-like structures (9 + 1 microtubules), *CO* connection, *DE* densification, *ER* endoplasmic reticulum, *F* flagellum, *HC* host cell, *IF* intravacuolar folds, *LM* limiting membrane of PV, *MI* mitochondrion, *MIH* mitochondrion of HC, *MP* micropore, *MT* microtubules, *N* nucleus, *NG* nucleus of the microgamete, *PF* perforatorium, *PV* ► **parasitophorous vacuole**, *RB* residual body, *RN* residual nucleus, *UF* underlying ► **fortification**, *UM* unit membrane, *VA* vacuolization

a large single ► **macrogamete** (looking like an ovum). In no case, however, is the question of the chronological order of meiotic reduction definitively solved; so the distribution of haploidy and diploidy is not yet quite clear (► **Chromosomes**). In piroplasms (e.g., ► *Babesia* spp. and ► *Theileria* spp.), gamete formation and fusion differ from those in other sporozoans and need still more investigation (Figs. 3, 4, and 5, pp. 544, 555).

In all specimens of parasitic protozoans with typical gametes, a complete ► **syngamy** can be observed, i.e., the differently determined gametes fuse completely, whether they include large (iso- or anisogametes) or only small (► **Microgametes**) amounts of cytoplasmic material. Syngamy always starts with the fusion of the limiting membranes (Figs. 4, 5, 6, 7, and 8, pp. 544–546), thus leading to a unicellular diplokaryon. Although karyogamy may be more or less delayed

Gametes: Protozoa, Fig. 2 TEM (a, c, d) and light (b) micrographs of developmental stages of microgamonts and microgametes. (a) ▶ *Sarcocystis sui hominis*: longitudinal section of microgametes connected to the residual body of the ▶ gamont (RB) by a short bridge (CO). The microgametes consist of the nucleus (N) forming a groove, within which the mitochondrion (MI) is situated, two free flagella (F) with a typical cross section (inset) and some microtubuli (MT) running below the ▶ cell membrane. At the gamete's tip, a stiff perforatorium (PF) is formed that helps to enter into the macrogamete. PV ▶ parasitophorous vacuole. × 20,000. (b) Microgamont of ▶ *Eimeria stiedai*

during formation of microgametes (MIG). NH nucleus of the host cell. × 1,000. (c) ▶ *Isospora* sp. from sparrow's intestine; formation of two microgametes from a single nucleus (N) in a microgamont. AF attached flagellum, DE densification = later nucleus a microgamont, F flagellum, N nucleus (remnant), NM nuclear membrane. (d) Cross section through the anterior tip of a microgamete of *Eimeria maxima*. Note the presence of the nuclear tip (N), the mitochondrion (MI), the attached flagellum (AF), and two rows of microtubules (MT, arrows). × 40,000. RB residual microgamont

depending on the species, no further fertilization can occur along the surface of such zygotes, whether a fertilization membrane (as in some eimerian species) is formed or not.

In ciliates (e.g., *Balantidium*), no typical gametes are produced, but two similar looking individuals (Conjugants) join temporarily for an

exchange of a “wandering” nucleus during ▶ conjugation. Similar processes may occur in other groups where sexual interchange has not yet been found or is reduced to a fusion of sister nuclei (▶ *Myxozoa*), which is called autogamy. Other hidden sexual processes are known from ▶ *Microsporidia*, where so-called meiospores

Gametes: Protozoa, Fig. 5 ▶ *Babesia* spp.; formation and fusion of gametes. 1–1.3 Formation of merozoites by ▶ **binary fission** (depending on the presence of fresh red blood cells in culture); this process does not occur in the tick's gut, where merozoites are dissolved. 2–2.5 Sexual processes. 2 Ovoid-spherical stages become gamonts and form protrusions (even in the vertebrate host blood). 2.1–2.2 Two types of ray bodies occur (one is more

electron lucent than the other) after probable divisions. This process starts after disruption of the erythrocyte. 2.3 Syngamy of gametes. 2.4 Opening along the attached membranes. 2.5 Fusion of the nuclei. *E* erythrocyte, *FU* fusing nuclei, *GA* gamont, *IN* in culture indefinite repeated division occur, *LS* labyrinthine structure, *ME* ▶ **merozoite**, *N* nucleus, *PT* protrusion, *RL* remnants of the labyrinthine structure, *RT* remnant thorn, *TH* thorn, *Z* zygote

may occur (e.g., ▶ **Amblyospora**). More sophisticated methods, however, will surely contribute to the knowledge of this neglected, but extremely important, phase of the parasite's life cycle.

In some groups of protozoans apparently, exchanges of DNA occur without a definite proof of fusion processes, which, however, may exist in low numbers and are thus not registered. Exchange experiments between

different clones showed that in ▶ *Trypanosoma* haploid, diploid, and hybrid stages occur in the life cycle, a fact which underlines the suggested fusions (Fig. 6, p. 547). In ▶ *Entamoeba histolytica*, DNA measurements proved that the tissue-invading magna-forms possess at least twice as much DNA as the intestinal minuta forms – is this fact an indication for a preceding fusion process?

Gametes: Ticks

The male ticks develop 500 μm long prospermia which mature via a complicated process (called capacitation = differentiation) within 24 h (after transfer to the female system) into a fertile stage (spermiophore). However, when having got contact to the female gamete (oocyte), only the nucleus of the male gamete enters, while the remainder of the sperm disintegrates. The prospermia of argasid ticks may measure up to 1 mm in length, those of ixodid ticks are shorter. Below the outer border of the prospermia many microtubule are arranged to guarantee shape and motility.

Gametes: Worms

Trematodes

The sperms of schistosomes are different from those of other trematodes. They possess a head-like thickening, which contains the electron dense nucleus. At the basis of the nucleus, a mitochondrion occurs and a basal body gives rise to a single axoneme which enters a long filament-like tail. The center of the axoneme only contains none, one, or two microtubules (Figs. 1, 2, and 3, pp. 548, 549). Beneath the single cell membrane 25–115 microtubules are lining the inner surface of the gamete. In other digenetic trematodes (e.g.,

Gametes: Worms, Fig. 1 Longitudinal section through the anterior end (head) of schistosomal sperms

Gametes: Worms, Fig. 3 Cross-section through sperms of schistosomes at different levels of the axoneme. Note the terminal portion of the nucleus (*black*)

Gametes: Worms, Fig. 2 Cross-section through the head of schistosomal sperms showing the nuclei and the peripheral microtubuli

Gametes: Worms, Fig. 4 Cross-section through sperms of *Clonorchis* in a non-nuclear region

in *Clonorchis*) two axonemes are formed instead of one in schistosomes (Figs. 4, and 5, p. 549). In *Paragonimus*-sperms two mitochondria occur. The female gametes of most trematodes are ovoid or spherical.

Cestodes

The male gametes of the cestodes are filament-like reaching a length of often 0.2 mm. They are limited by a single cell membrane, which is lined inside by 25–40 microtubules (Fig. 6, p. 550). The nucleus is situated in the central portion and

Gametes: Worms, Fig. 5 Cross-section of sperms of *Clonorchis* in a nuclear region

Gametes: Worms, Fig. 6 Cross-section through the sperms of *Hymenolepis nana* (Cestoda) at different levels

is accompanied by the single axoneme, which has only a single central element. Mitochondria were not seen, acrosomal structures are lacking, too. The female gametes are in general spherical.

Nematodes

The gametes of nematodes are described and pictured in the keyword ► [nematodes](#).

Gametocyte

Other word for ► [gamont](#), i.e., stage preceding gametes.

Gamogony

Sexual phase in the life cycle of ► [Coccidia](#) which proceeds in general as ► [oogamy](#) with macrogametes and ► [microgametes](#) (Gametes, ► [Eimeria](#), ► [Mitochondria](#)/Fig. 1E).

Gamont

Stage preceding the gametes (in Protozoa).

Gaster

Heinz Mehlhorn

Disease due to infestation with ► [Gasterophilus](#) species, see Table 1.

Gasterophilosis, Table 1 *Gasterophilus* species and control measure

Parasite	Host	Symptoms	Country	Therapy Products	Application	Compounds
<i>Gasterophilus haemorrhoidalis</i> (Nose or lip bot)	Horse		Worldwide	Eqvalan (Merial)	Paste	Ivermectin
<i>Gasterophilus inermis</i>	Horse		Europe, Africa, Asia			
<i>Gasterophilus intestinalis</i> (Common bot)	Horse	Most of the time asymptomatic; stomatitis, eating and chewing problems, erosions, ulcera, and dilatation of the stomach, chronic duodenitis, proctitis	Worldwide	Equimax (Virbac)	Paste	Abamectin + Praziquantel
				Eqvalan/gold Merial	Paste	Ivermectin
				Neguvon (Bayer)	Solution	Trichlorfon
				Quest (Zoetis)	Gel	Moxidectin
<i>Gasterophilus nasalis</i> (Throat bot)	Horse		Worldwide	Zimecterin (Merial)	Paste	Ivermectin + Praziquantel
				Equimax (Virbac)	Paste	Abamectin + Praziquantel
				Eqvalan/gold Merial	Paste	Ivermectin
				Neguvon (Bayer)	Solution	Trichlorfon
<i>Gasterophilus nigricornis</i>	Horse			Quest (Zoetis)	Gel	Moxidectin
				Zimecterin (Merial)	Paste	Ivermectin + Praziquantel
				Zimecterin (Merial)	Paste	Ivermectin + Praziquantel
<i>Gasterophilus pecorum</i>	Horse		Europe, Africa, Asia	Zimecterin (Merial)	Paste	Ivermectin + Praziquantel

Gasterophilus

Name

Greek: *gaster* = stomach, *phil* = loving it.

Important Species

- *G. intestinalis* (eggs are deposited all over the host's (equids) body), about 900 in 3 h
- *G. haemorrhoidalis*, *G. nasalis* (eggs are found at lips)
- *G. inermis* (eggs on the hair of cheeks)
- *G. pecorum* (eggs are deposited on host's food), up to 2,000 per female

Adults do not feed, larvae hatch in the case of *G. intestinalis* within 7–14 days.

Human infections may occur after contact with infested horses with *G. nasalis*, *G. intestinalis* and *G. haemorrhoidalis*. The larvae penetrate human skin and migrate in a serpentine causing a line. Thus this myiasis is called *myiasis linearis*. Adults of *G. intestinalis* (syn. *G. equi*) reach a length of 1.8 cm (Figs. 1 and 2; page 551) and appear reddish-yellow, brown-black. As adults they do not feed anymore. After mating the females, which possess a pointed terminal end being bended below the abdomen, clue up to 5,000, 0.2 mm long eggs at the hair of horses. After 5–10 days the larvae hatch from the egg and enter the mouth actively or are transported there during the licking of the horse. In the stomach the larvae molt twice and grow up to 2 cm as larva III; this stage appears red and is excreted 8–10 months after infection with the faeces. Pupation occurs immediately on/in the soil. After 3–8 weeks the adult flies hatch from the puparium (during June). Their time of activity is July and August in Europe. ► [Diptera](#).

Gasterophilus, Fig. 1 Diagrammatic representation of the dorsal side of an adult female of *Gasterophilus intestinalis*. The pointed posterior end is bended below the abdomen

Gasterophilus, Fig. 2 Larvae of *Gasterophilus intestinalis*, that are attached to the stomach wall of a horse

Gasterophilus pecorum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

While six species of the genus ► *Gasterophilus* glue their eggs at horses, *G. pecorum* glues its eggs at grass. The hatched larva 1 enters the

mouth of the horse and becomes anchored between the teeth; later the larva 2 penetrates the esophagus wall and the larva 3 is finally excreted within the feces. Masses of such larvae may kill equids, elephants, and rhinoceros.

Gastrodiscoides hominis

► [Digenea](#).

Gastrodiscoides species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *gaster* = stomach; *discoides* = disk-like.
Latin: *hominis* = belonging to humans;
aegyptiacus = Egyptian. English: Amphistomal
flake.

Geographic Distribution/Epidemiology

In India, Indochina, Java, Philippines, Japan about five to ten millions of humans are infected according to the estimations of the WHO. Horses in North Africa.

Morphology/Life Cycle

The digenetic flukes *G. hominis* and *G. aegyptiacus* reach a size of 5–10 × 5 mm and parasitize in humans in the colon respectively in horses (*G. aegyptiacus*). Their shape is characterized by a circularly enlarged posterior body region. The ventral sucker is placed like in all other amphistomid flukes at the posterior end (see ► [Paramphistomum](#)). The life cycle runs

similar to that of ► [Fasciolopsis buski](#). Rats and pigs function as “reserve hosts.”

Symptoms of Disease

Only in cases of mass infections diarrheas are initiated.

See ► [Fasciolopsis buski](#), since most criteria and characteristics are very similar.

Gastrointestinal Hormones

General Information

Gastrointestinal hormones like gastrin, cholecystokinin (CCK) and vasoactive intestinal peptide (VIP) are small peptides of 4–58 amino acids. Most of these hormones are sulfated.

Physiological Function

Gastrointestinal hormones are not part of a hierarchical system like the hypothyseal-gonad or -thyroid, or -adrenal gland axis. They are released by neurotransmitters, other hormones of the gastrointestinal tract and by components of the food. Interestingly, these hormones are also produced in the central nervous system and their functions are different, depending on the localisation. For example, CCK increases the release of hormones and enzymes from the pancreas and also contracts the gall bladder, but in the brain it is an important sensor for satiety.

Clinical Relevance

Infection with gastrointestinal ► [nematodes](#) is an important cause of impaired productivity in all domestic ruminants (Alimentary System Diseases, Ruminants). Changes in feed intake and gastrointestinal functions are essential mechanisms for these losses. Gastrin levels increase after infection, as well as the pH in the abomasum. Quite often, but not regularly, there is also an increase in serum pepsinogen. These different effects finally lead to ► [hyperplasia](#) and hypergastrinemia. In some gastrointestinal helminths, gastrointestinal hormones have been demonstrated by immunocytochemistry but the function of these parasitic hormones is unknown so far, with the exception of a vasoactive intestinal peptide (VIP) from the nematode *Nippostrongylus brasiliensis*. This hormone is part of the excretory/secretory material and it inhibits the amplitude of contractions of the intestinal tract as efficiently (in the pM range) as the corresponding vertebrate hormone. Since VIP is known to inhibit food intake and to stimulate ACTH and growth-hormone release in the brain, the nematode VIP might therefore have additional advantages for the parasite.

Pathology

Infection of ruminants with adult worms (► [Haemonchus contortus](#), resp. ► [Ostertagia circumcincta](#)) leads to rapid responses (increase in serum pepsinogen and gastrin as well as abomasal pH) within less than a day, whereas with larval stages there is a lag phase of 4 to 5 days, though finally there is the same degree of response and also of hypergastrinemia. It is speculated that excretory/secretory products of adult worms lead to this cascade of events. Removal of the adult worms by treatment with antihelminthic agents rapidly normalises gastrin, pepsinogen and abomasal pH. The role of CCK for sensing satiety was demonstrated by the application of CCK which depressed short-term feed intake only in infected animals and also by a CCK antagonist which, after central infusion, increased

short-term feed intake. The effect was more pronounced in infected animals than in controls.

Gastrotaenia

Genus of the tapeworm family Hymenolepididae. *Gastrotaenia* sp. reaches a length of 13 mm and is found in the muscular stomach of ducks and swans. Intermediate hosts are copepods.

Gastrotaenia cygni

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Gastrotaenia cygni are gizzard cestode species in North American birds (e.g., in the blue-winged teal *Anas discors*). Occasional human infections had also been described.

Data bank for gene sequences.

Géné's Organ

Géné's organ is common to all female ► [ticks](#). It is found just above the position at which the capitulum is joined to the idiosome, in the camerostomal fold of ixodid ticks, the camerostomal depression of argasid ticks, or anterodorsally ventrad of the pseudoscutum in nuttalliellids. During ► [oviposition](#), Géné's organ emerges through an aperture to give each egg a waxy surface, as a final waterproofing. The ► [porose areas](#) of female ixodid ticks (► [Ticks](#)/Fig. 6), whose function was not known for a long time, appear to act in conjunction with Géné's organ by producing inhibitors of the autoxidation of the unsaturated egg wax lipids (► [Ticks/Reproduction](#)). Terminal portion of the ixodid tick ovipositor system. Here the eggs were covered by a clueing layer, which protects the egg from drying when deponed onto the floor. This

layer enables the rather undisturbed development of the larvae inside.

Genital System Diseases, Animals

Arwid Dauschies¹ and Jozef Vercruysse²

¹Veterinärmedizinische Fakultät, Institut für
Parasitologie, Universität Leipzig, Leipzig,
Germany

²Laboratory of Parasitology Faculty of Veterinary
Medicine, Ghent University, Merelbeke, Belgium

Parasitic infections of the genital tract are of major economic importance (Table 1), particularly those caused by the widely distributed protozoan parasites, ► [Toxoplasma gondii](#), ► [Neospora caninum](#) (syn. ► [Hammondia heydorni](#), ► [Sarcocystis](#)), and ► [Trichostrongylus axei](#) which are major causes of reproductive failure in ruminants. Moreover, any parasite that induces general disease may have negative impact on pregnant animals.

T. gondii infections are ubiquitous throughout the world and are an important cause of ► [abortion](#) in small ruminants. In fact, the parasite may invade all nucleated cells in nearly all warm-blooded animals, and the clinical picture in a particular host species depends on whether or not the malfunction of a specific organ is related to this. However, in the vast majority of cases, infections remain asymptomatic.

Infection with *T. gondii* may cause early embryonic death and resorption, fetal death and mummification, abortion, stillbirth, and neonatal death or birth of weak offspring. Severity of infection is associated with the stage of gestation at which the pregnant animal becomes infected; the earlier in gestation, the more severe the consequences. During initial exposure of pregnant ewes and does, the parasite primarily invades the placenta and infects, at any gestational age, the fetus, with or without fetal death. Abortion is generally caused by necrosis of the cotyledons of the placenta. Congenital infection mainly affects the brain of the fetus, and lambs or kids born alive may show signs of ► [encephalitis](#). In pigs and

Genital System Diseases, Animals, Table 1 Parasites affecting the genital system of domestic animals (according to Vercruysse and De Bont)

Parasite	Host	Location	Clinical presentation	Principal lesions
Protozoa				
<i>Besnoitia besnoiti</i>	Cattle	Testicles	Infertility	Orchitis
<i>Neospora caninum</i>	Cattle, sheep, goat, horse, dog, cat	Neural tissues	Abortion, neuromuscular signs in congenitally infected calves	Encephalitis in transplacental infected fetuses
<i>Sarcocystis</i> spp.	Cattle, sheep, goat, pig	Vascular endothelium of placenta, fetus	Abortion	Placentitis
<i>Toxoplasma gondii</i>	Sheep, goat	Placental cotyledons, fetus	Abortion	Necrosis in villous part of cotyledons, leukoencephalomalacia in congenitally infected lambs or kids
<i>Tritrichomonas foetus</i>	Cattle	Vagina, cervix, uterus, oviduct, preputium	Early abortion, sterility	Vaginitis, endometritis, balanoposthitis
<i>Trypanosoma equiperdum</i>	Horses	Genitalia, skin, nerves	Genital phase: mucoid, vaginal or urethral discharge, nymphomania, micturition, rarely abortion	Edema and inflammation of genitalia with ulcers, pigmentation of vulva or penis

dogs, cases of congenital toxoplasmosis have been reported, and clinically affected animals often show respiratory signs. *T. gondii* is apparently not a significant fetal pathogen in cattle and horses.

► *Sarcocystis* spp. are common, ubiquitous, sporozoan parasites of herbivores, but they rarely cause clinical signs or abortions in infected animals. Acute forms of sarcocystosis are associated with the massive development of schizonts in endothelial cells of blood vessels. The clinical signs include high fever, ► [anorexia](#), anemia, ataxia, and loss of weight, sometimes with high mortality rates. *Sarcocystis* spp. have occasionally been reported as causing abortion in cattle, sheep, goats, and pigs. In some cases, the absence of schizonts from the fetus suggests that the abortion is caused by maternal failure. In other cases, where the aborting mother may be otherwise normal, the extensive development of schizonts in the endothelial cells throughout the fetal tissues and

within the placenta suggest that abortion is directly caused by the parasitic infection. It is uncertain whether some reported cases of *Sarcocystis* abortion in cattle, in fact, are *Sarcocystis* or possibly *Neospora* infections.

N. caninum, which has long been misidentified as *T. gondii*, is now known to occur in a wide range of host species, including dogs, cats, horses, cattle, sheep, and goats. Dogs have been identified as definitive hosts. Clinical manifestations of ► [neosporosis](#) have mainly been observed in cattle and dogs. Transmission occurs orally and via the transplacental route. *N. caninum* has a predilection for the central nervous system and skeletal muscles, generally leading to encephalomyelitis and polymyositis. In cattle, neosporosis is regarded as a major cause of abortion, particularly among dairy cattle. Although fetal death probably occurs throughout the gestation period, cows only abort from 3 months of gestation to term. It is likely that 1–2-month-old fetuses are killed in

utero, resorbed, and the cow returns to heat again. Fetuses which die in utero may be resorbed, mummified, aborted, or stillborn. *N. caninum* is most often demonstrable in the brain and heart of the fetus and rarely in other organs, including the placenta. Some congenitally infected calves may be born with signs of neuromuscular dysfunctions, while others may be born clinically normal but chronically infected. In aborted fetuses, the major lesion is a multifocal, necrotizing, non-suppurative encephalomyelitis. *Besnoitia besnoiti* occurs in cattle in Southern Europe, Africa, and Southeast Asia. Lesions, if any, are mainly confined to the skin and mucosa of the upper respiratory system. As the infection progresses, sterility (aspermatozoogenesis) in males may appear caused by necrotizing orchitis, and these animals end up with atrophy and induration of the testes.

Trichomoniasis is an important venereal disease of cattle caused by the flagellated protozoan *T. foetus*. In bulls infections usually go unrecognized. However, they remain chronically infected and transmission of the parasite to heifers or cows occurs at coitus. In the female, a primary infection invariably causes a vaginitis of varying intensity, with swelling of the vulva and vaginal discharge. Thereafter the parasites migrate upward through the cervix and invade the uterus. The inflammatory changes in the endometrium and cervix are relatively mild and nonspecific, although the exudate, mucopurulent in character, may be rather copious. *T. foetus* does not prevent conception as such, but endometritis and uterine catarrh prevent proper fertilization and result in aberrant estrus cycles and repeat breeding. Trichomonal abortion may occur at any time but usually takes place early in gestation. Embryonal or fetal death may be followed by retention and sometimes pyometra and inflammation of the oviduct which occasionally result in permanent infertility. Unlike bulls, infections are self-limiting in females, with clearance of parasites after approximately 95 days.

► **Dourine** is a chronic venereal disease of horses caused by *Trypanosoma equiperdum*. The infection occurs in all species and breeds of Equidae, but not with the same intensity. Donkeys

and mules are more tolerant to the infection than horses, while among the latter thoroughbreds and imported horses tend to be more susceptible to the disease than native horses. Unlike other species of trypanosomes, *T. equiperdum* is transmitted by coitus. It may take several months before clinical signs appear, by which time the infection may have spread significantly over the horse population. *T. equiperdum* is a tissue parasite and infects primarily the mucosa of the genital organs, the skin, and nervous tissues. The disease which is insidious in nature, affects both stallions and mares. It usually progresses through three distinct phases. A first phase marked by swelling of the external genitalia is followed by an urticarial phase visible on the skin. These two phases may last several months to several years, during which time the animal gradually becomes cachectic. A third, invariably fatal nervous phase characterized by incoordination and paralysis occurs in some horses. The genital phase is initiated by a mucoid vaginal or urethral discharge, ► **nymphomania**, and a mild fever with ► **edema** of the genitalia. Abortion in cattle associated with *T. brucei* or *T. congolense* infection (Nagana, African trypanosomiasis) has been reported, and this disease may also reduce fertility by altering testicular steroid production and sperm quality in bulls and causing atrophy of the ovaries in cows.

In horses, larvae of the ► **nematodes** ► *Strongylus vulgaris* and *S. edentatus* have occasionally been found migrating into the testes, leaving such lesions as inflamed, hemorrhagic migratory tracts. In warm climates, larvae of *Draschia megastoma*, *Habronema muscae*, and *H. majus* deposited near the prepuce by the intermediate host flies (housefly *Musca domestica* and the ► **stable fly** *Stomoxys calcitrans*) burrow into the dermis and cause extensive granulomatous inflammation. The infestation known as “summer sores” is more common in geldings (accumulation of smegma) than in stallions.

Therapy

See treatment of the various species: ► **chemotherapy**, ► **drugs**.

Genome Sizes

► **Nucleic Acids**, ► **Chromosomes**. The genome of parasites is much larger/bigger than that of bacteria. While *Escherichia coli* has 4.2 Mb, reach protozoans 9.4 (*Babesia bovis*), 12 Mb (*Giardia*), 20 Mb (*Trypanosoma brucei brucei*), or even 80 Mb (*Toxoplasma gondii*). Worm genomes become even much bigger, i.e., 150 Mb are reached in the case of *Onchocerca*, 270 Mb in schistosomes. The same size range is found in mosquitoes (280 Mb), while small mammalia (like mice) have 2700 Mb.

Genomics of Parasites

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Hundreds of thousands of genes have been described in different parasites; however, their function remains (until now) mostly in the dark, since parasites are clearly different from free-living species. Thus several authors claim that the genes of parasites probably have obtained novel functions, which need primarily to be studied. For example, the number of protein-coding genes found within parasites ranges from 3,800 in the developmental stages of the protozoan parasite ► *Cryptosporidium parvum* up to 21,800 in the adult nematode ► *Haemonchus contortus*. Thus studies must select those gene activities which are important, e.g., those steering invasion, survival, pathologic effects, etc.

Genotype

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek – *gignesthai* = developing; *typos* = type.

In contrast to genetic sciences, where this term is used to describe all genomic components of an organism, in parasitology this term is used for variations inside of members of a species when differing in important genetic characteristics.

Geographic Distribution

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Like all living species, parasites have adapted to particular ► **environmental conditions**. No parasite species exists everywhere on earth. For a parasite to exist at any one place, there needs to be a suitable host and a suitable environment for transmission.

The expression “suitable host” implies several constraints: not only must the host be “qualitatively” present (i.e., a susceptible population) but also quantitatively (i.e., a density of hosts allowing sufficient production of larval stages and transmission); in heteroxenous life cycles,

Geographic Distribution, Fig. 1 Current distribution of *Schistosoma mansoni* and ► *S. haematobium*, as explained by their vector distribution: *S. mansoni* and *S. haematobium* were both introduced into the New

World during the sixteenth and seventeenth centuries but only the first one was compatible with local snails and became established (From Combes, 1995, modified)

the constraints are multiplied by the number of different host species necessary for the completion of the cycle.

The expression “suitable environment for transmission” implies other constraints, because (with very few exceptions like *Trichinella*) parasites spend a part of their life outside the hosts and have, like all organisms, particular requirements such as range of temperature, presence of water, etc.

The geographic range of a particular parasite is usually constrained by a limiting factor, which is not always easy to identify (cf. maps

added to several life cycles). When several host species are required for the development of a parasite species, this species can exist only where all these host species coexist. This explains why parasites with simple life cycles adapt themselves to new environments better than parasites with complex life cycles. In the latter case, it is rare that all the conditions are met. For instance, when schistosomes were transported into America with the slave trade (Fig. 1), only one species of African schistosome found a convenient mollusk vector and became established (► [Specificity](#)).

Geographic Zones of Occurrence of Diseases

Agents of disease are found in different numbers in four different zones:

- (a) **Endemic zone:** infections are found the whole year.
- (b) **Epidemic zone:** outbreaks occur at different intervals.
- (c) **Incursive zone:** disease and its agents are only found occasionally.
- (d) **Exterior zone:** here the agents of disease were not yet found.

Germanium

Ovary of Platyhelminthes Digenea.

Giant Cells

A granulomatous reaction is introduced by multinucleated giant cells in human brain infected with *Acanthamoeba* or *Balamuthia* amoebae (► [GAE](#)). This reaction may not be present in cases of immunosuppressed patients. A similar reaction occurs in the liver of patients with schistosomiasis. There the remnants of the eggs of the schistosomes are finally engorged by such giant cells, which occur at the end of a strong granulocytic reaction in the liver. ► [granulomes/pathology](#).

Giardi, Alfred (1846–1908)

French zoologist and describer of many protists.

Giardia duodenalis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

The genus and species name honors famous scientists (Alfredo Giardi: 1846–1908 and W. D. Lambl: 1841–1895). Latin: *duodenalis* = duodenum = anterior portion of the small intestine.

Geographic Distribution/Epidemiology

Worldwide; in tropical regions especially increased numbers occur; it is estimated that worldwide several hundred thousands of humans are constantly infected. These numbers will increase, since cross-infection with species/sub-species respectively strains (which occur in animals) are now proven.

Morphology/Life Cycle

G. lamblia occurs in two stages: trophozoites and cysts (Figs. 1, 2, 3, and 4). The trophozoites appear pear shaped or drop like; their flattened ventral side contains a large adhesion system (called discus) and the typical eight flagella, which are symmetrically arranged (Fig. 5). The trophozoites reach a length of about 20 µm and a width of 7–10 µm. In contrast to their flattened ventral side (whereby they attach at the microvilli of the host's duodenum), the dorsal region appears arch shaped (hump-like) protruded. Inside trophozoites two ovoid nuclei occur. Their genome is absolutely identical indicating that this organism had its evolutionary roots in a “forgotten cell division.” Reproduction occurs by longitudinal binary fusion, which is typical for flagellates. Prior to the division of the cell body the flagella

***Giardia duodenalis*, Fig. 1** Light (a, b) and transmission electron microscopy (c, d) micrographs of trophozoites (a, c, d) and a cyst (b) of *Giardia duodenalis*. (a) Two trophozoites showing each two nuclei and their flagella (Giemsa stain). (b) Unstained cyst containing the cytoplasm with

retracted flagella. (c) Several trophozoites are attached at the surface of the microvilli of the host's intestine. At some places detached stages have left depressions along the intestinal surface. (d) Ventral side of a trophozoite showing the typical sucker like hold-fast system (called discus)

are doubled, so that stages with 16 flagella can be seen. This stage of early division appears heart like. After detachment of the duodenal wall of the host the trophozoites are transported within the feces to the region of the colon, where they retract their flagella and excrete a thin cyst wall. Inside this cyst, which appears ovoid and measures 10–14 μm in length, the nuclei are doubled, so

that each cyst appears with 4 nuclei (Figs. 1a, 2, 3, and 5). According to modern molecular biological investigations there are no more strict species borders between the different strains of *G. duodenalis*, which are described in numerous hosts (see Table 1). Thus these variations are called types, and two groups (A, B) have been defined to occur in different hosts.

Giardia duodenalis, Fig. 2 Life cycle of *G. duodenalis* (for other species see Table 1 and ► *Diplomonadida*, Table 1). 1 Oral uptake of cysts after fecal contamination of food. 2 trophozoites excyst in small intestine and may divide by ► binary fissions. 3 Trophozoites are attached to the surface of the intestinal villi; ► pinocytosis occurs at their

Giardia duodenalis, Fig. 4 *Giardia duodenalis*. Transmission electron micrographs of a tangential section of the ventral side, which is formed by rows of microtubules. F flagellum, VD ventral disc

Symptoms of Disease: (Giardiasis)

In many cases infections with *Giardia* stages remain symptomless, or only low-graded nonspecific intestinal disturbances are noted. However, under certain conditions (e.g., lack of disaccharides of the intestinal wall, reduced production of immunoglobulin A, T-cell deficiency, occurrence of other intestinal diseases) severe symptoms of a giardiasis may occur. In these cases often are found nausea, vomiting, abdominal swellings, abdominal pain with cramp-like phases, and considerable intermittent watery-slimy diarrheas.

In the case of children and of AIDS patients these diarrheas may introduce a life-threatening loss of water. Constant infections of children may imply reduction of their development. This occurs because giardiasis causes malabsorption of the parasitized host cells – especially of vitamins from the food.

Diagnosis

Although trophozoites may also be found in fresh diarrheic human stools or in feces of animals, diagnosis is mainly based on the discovery of cysts. Thus cysts can be seen best after employment of concentration methods such as ► [S.A.F.C.](#) or ► [M.I.F.C.](#) respectively ► [flotation](#) in saturated NaCl solutions. However, it must be considered that excretion of cysts (Figs. 3, 4, and 5) does not occur permanently, so that it is recommended to investigate the stool at several consecutive days.

Infection

Infection starts after oral uptake of cysts, which are ingested with fecally contaminated food or water. Since those cysts are very tiny, they may also become transported by wind or by flies from feces to food or drinking water. Since the *Giardia* types A and B occur as well in humans as in animals (Table 1), the disease fulfills the requirements of a typical zoonosis.

Prophylaxis

Cooking the food and boiling the drinking water interrupts any transmission.

Incubation Period

Three to twenty-one days (mean about one week).

Prepatent Period

Three to four weeks.

Patency

Eventually years due to repeated self-infections.

Giardia duodenalis,

Giardia duodenalis, Table 1 *Giardia* species (groups)

Species group	Size (µm)	Hosts
<i>G. duodenalis</i> (Assemblage A)	10 × 22	Many wild and domestic animals, humans
<i>G. enteritica</i> (Assemblage B)	10 × 22	Humans, primates, dogs, some wild mammals
<i>G. agilis</i> (Assemblage C/D)	9 × 4	Amphibians
<i>G. muris</i> (Assemblage C/D)	13–19 × 8–11	Rodents
<i>G. ardeae</i> (Assemblage C/D)	8 × 15	Birds
<i>G. psittaci</i> (Assemblage C/D)	8 × 15	Birds, parrots
<i>G. microti</i> (Assemblage C/D)	12 × 8	Rodents
<i>G. canis</i> (Assemblage C/D)	10–17 × 7–10	Dogs, canids
<i>G. cati</i> (Assemblage F)	10–17 × 7–10	Cats
<i>G. bovis</i> (Assemblage E)	11 × 19	Cattle, other ungulates
<i>G. simondi</i> (Assemblage G)	14 × 10	Rats

Therapy

Recommended treatment is based on the use of metronidazole (3 × 400 mg daily for 4 days) in the case of adult patients. Children should be treated with 15 mg/kg bodyweight for 5 days. Healing effects reach only 90 %. Therefore a repeated treatment has to be done in case clear symptoms persist or start again some days/weeks after the first treatment phase. The use of nitroimidazoles during pregnancy is not allowed. Symptomatic treatment is then recommended by drinking larger amounts of water and eating carbohydrate-rich food.

Giardia lamblia Ploidy

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Uninuclear protozoans in general show a diploid genome possessing two sets of each type of chromosomes. Due to its possession of two nuclei, *Giardia lamblia* is tetraploid. This status makes it difficult to start genetic manipulations. However,

the use of a *Giardia*-tailored Cre/lox P method offered the chance to fix genetic insertions or deletions in *Giardia* chromosomes. Cre/lox P is a bacteriophage P1-tool, which has already been used to manipulate many other different organisms.

Giardia: Sexual Activities

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The trophozoites of ► *Giardia lamblia* have two nuclei as trophozoites, but cysts contain four nuclei. In some studies, it was shown that two nuclei in the early cysts stage may fuse, indicating a sexual process. Other papers showed sexual reproduction with outcrossing. However, it is not understood whether there is a meiotic or a parasexual cycle.

Giardiasis, Animals

Pathology

Giardia species occur in dogs and cats, and giardiasis may represent an important problem in these hosts. It causes ► [anorexia](#), depression, and

a mild recurring ► [diarrhoea](#) consisting of soft, light-coloured stools with a characteristic “oat-meal” texture, frequently containing mucus. Growth retardation and cachexia may occur. The mechanism by which giardial malabsorption and diarrhoea occurs is unclear. Epithelial damage, increased turnover of epithelial cells, villous shortening, and disaccharidase deficiency have all been reported as manifestations of giardiasis.

Giardia spp. are usually non-pathogenic inhabitants of the intestine of horses, cattle, sheep, and goats. However, they may cause diseases under certain circumstances, such as in animals which are immunocompromised, malnourished, or very young.

Immune Responses

Giardiasis, Man

Pathology

Giardia lamblia is a binuclear, pear-shaped flagellate which lives in the duodenum and upper small intestine, where it is closely applied or attached to the epithelium by means of a suction disk. Ultrastructural examination of a biopsy of the small intestine often shows the epithelial ► [microvilli](#) to be destroyed at the attachment sites of the flagellates. Acute infections are

usually of short duration with ► [diarrhoea](#) and epigastric distress which subsides with the development of immunity. ► [Chronic infections](#) occur in patients with low or absent IgA, IgG, or IgM. In these patients the intestinal villi are often blunted from loss of epithelium which regenerates inadequately. The lamina propria is heavily infiltrated with lymphocytes and granulocytes. Diarrhoea, ► [weight loss](#), and intestinal malabsorption with flatulence accompany chronic infections. The ► [trophozoites](#) can be found in diarrhoeic stools, by duodenal aspiration or biopsy. The four-nucleate cysts (► [Giardia lamblia](#)/Fig. 3) are found in stools.

Immune Responses

The establishment of animal models and the production of the whole life cycle of the parasite *in vitro* have greatly facilitated the characterization of stage-specific antigens as well as of analyzing the contribution of humoral and cell-mediated immune responses in the control of the infection. Most of the current knowledge comes from four different sources: (1) *in vitro* studies with axenically grown ► [G. lamblia](#) trophozoites and immune cells from different hosts; (2) studies with *G. lamblia*-infected mice or gerbils; (3) experiments with *G. muris*-infected mice; and (4) the analysis of immune responses in *Giardia*-infected humans.

Innate Immunity

Since neutrophils are circulating blood cells, they are generally considered to play only a minimal role in intestinal infections. However, these cells are able to migrate like ► [amoebae](#) through small cracks in vessel linings to the exterior, where they eventually infiltrate tissues such as epithelial layers of the intestinal tract. It has been shown that certain products of neutrophils, cryptidins, and cationic neutrophil peptides, possess anti-giardial activity. The content of granules together

with antibodies reduces parasite infectivity and antibody-dependent cytotoxicity (► ADCC) was demonstrated with human peripheral blood neutrophils *in vitro*. Since all these anti-giardial effects of neutrophils have been analyzed only *in vitro* so far, the functional role of these cells *in vivo* remains to be elucidated. Although in mice infected with *G. muris* there was only a small rise in mucosal mast cell numbers, inhibition of mast cell products by cyproheptadine enhanced the infection.

B cells and Antibodies

An important function of antibodies in the control of giardiasis is suggested by more severe infections in patients with hypogammaglobulinaemia. In B-cell-deficient mice, unable to mount an anti-*Giardia* Ig response, the infection with *G. lamblia* could not be resolved and antigenic diversification within the parasite population occurred in an unusually slow manner. Several studies have additionally demonstrated antibody-mediated killing of *Giardia* trophozoites *in vitro*, which is not in all cases complement dependent. The most important Ig for the control of giardiasis is IgA. The appearance of secretory IgA in the intestine correlates with the elimination of the parasite from the small intestine, but the effect of Ig subclass is complement-independent since IgA lacks C1q-binding sites in its Fc region required for the activation of the classical complement pathway. IgA may thus mediate its function in a complement-independent manner, e.g., by binding to trophozoite surface proteins thereby causing detachment and aggregation of the parasite. However, a functional role of complement should not be ruled out since (1) proteins of the complement cascade are synthesized by epithelial cells of the intestinum and (2) the alternative pathway of complement activation may be operative. Certain surface molecules, e.g., in the sucking disc of the parasite as well as

metabolites released by trophozoites are able to activate the alternative pathway.

T cells

There are few studies on the role of specific T cells in the defense against *Giardia*. The latent and acute phases of *G. lamblia* infection are accompanied by an increase of CD8⁺ cells among IELs while in the elimination phase this population decreases and CD4⁺ cells increase significantly. Since trophozoites are killed by oxidative-burst mechanisms stimulated in macrophages via IFN- γ , it was tempting to speculate that T cells producing this cytokine might be involved in the control of parasite replication.

In addition, IFN- γ leads to enhanced phagocytosis of *Giardia* trophozoites by macrophages. Comparing the antibody and cytokine response in relatively resistant B10 mice and more susceptible BALB/c mice it was found that B10 mice produced IgG2a while BALB/c mice produced IgG1 after *G. muris* infection, suggesting differential involvement of Th1 and Th2 cells. When lymphocytes from mesenteric lymph nodes were stimulated *in vitro*, only those of B10 mice produced measurable amounts of IFN- γ . The application of neutralizing antibodies against IFN- γ to B10 mice resulted in an enhanced intensity of infection, arguing for a protective role of Th1 cells in this parasitic infection.

Immunopathology

The killing of the parasite can lead to injury as shown, for example, in co-culture experiments with enterocytes and activated macrophages from the gut of mice infected with *G. lamblia*. It is not clear, however, if villus atrophy and crypt ► hyperplasia observed in response to infection with *Giardia* as well as the phenomena of

maldigestion and malabsorption are direct consequences of the parasite load or caused by the host's immune response. Antigenic extracts of *G. lamblia* containing proteins of 32–200 kDa transiently suppressed the activity of dissaccharidases when gerbils were challenged with this fraction. It has been speculated that this short-lived effect could be mediated by lymphokines and/or mediators released by mast cell, neutrophils, or macrophages.

Evasion Mechanisms

Only recently has the possible involvement of antigen-variation in establishing a *Giardia* infection been noticed. The antigens involved belong to a family of variant-specific surface proteins (VSGs), which are unique, cysteine-rich zinc-finger proteins. After inoculation of a single *G. lamblia* clone expressing one ► [VSG](#) into mice or humans, the original VSP is gradually replaced by many others beginning 2 weeks post-infection. Selection by immune mechanisms is suggested because (1) switching occurs at the same time that antibodies are first detected and (2) the antigenic switching does not occur in SCID mice.

The ► [antigenic variation](#) of *Giardia* parasites may increase the chance of successful initial infection or reinfection.

Main clinical symptoms: ► [Abdominal pain](#), Slimy non-bloody, diarrhoea, malabsorption.

Incubation period: 3–21 days.

Prepatent period: 3–4 weeks.

Patent period: Years.

Diagnosis: Microscopic determination of trophozoites and cysts in faecal samples.

Prophylaxis: Avoid contact with human or animal faeces.

Therapy: Treatment see ► [Antidiarrhoeal and Antitrichomoniasis Drugs](#).

Giemsa Stain

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This staining was developed by Gustav Giemsa as a classic blood film stain for peripheral blood smears (e.g., *Plasmodium* species) and bone marrow smears (e.g., *Leishmania* species). Erythrocytes stain red to pink, cytoplasm of lymphocytes appears blue, monocyte cytoplasm stains pale blue, while chromatin of leucocytes appears in magenta. Besides protozoans and “white” cells, Giemsa stain is also able to stain the histoplasm of fungi and, e.g., bacteria of the *Chlamydia* type. The staining of thin blood smears and thick films is performed as follows:

Thin Film/Blood Smear

A small droplet of blood is spread with the help of a glass slide in order to get the thinnest film (Fig. 1, above, middle) and it is air-dried before the following procedure is done:

1. Fixation of the blood smear for 3 min by covering it with absolute methanol
2. Drying at the air
3. Staining with the help of Giemsa stain (see below) for 30 min
4. Cleaning the slide by submersion into water and drying
5. Covering the slide with a drop of Eukitt or other covering media and adding a cover slide

Thick Film

1. A droplet of blood is placed onto a glass slide.

Giemsa Stain, Fig. 1 Diagrammatic representation of the preparations of a blood smear (both drawings above) and a thick droplet (below)

2. By stirring this droplet by help of another slide coagulation is avoided (Fig. 1, below).
3. After drying the droplet is not (!) fixed but the slide is placed into water, whereby the erythrocytes are hemolyzed and the parasites are set free.
4. As soon as the droplet is dry, it is stained by help of the Giemsa solution.

Giemsa Stain

Solution of 0.3 ml (Azur-Eosin-Methylene blue solution) (e.g., Merck product 8204) plus 10 ml

Weise buffer (0.49 g KH_2PO_4 , 1.14 g HPO_4 dissolved in 1 l Aqua bidest).

Gigantism

When parasitized, several snail species grow up considerably in order to compensate losses due to parasites (e.g., in the mud snails *Hydrobia ulvae* and *H. ventrosa* when parasitized by trematode stages).

Gigantobilharzia

In contrast to its name this genus includes very thin (filament-like) schistosomes of gulls. They are about 1.2 cm long, look similar as males and females, and have reduced mouth and ventral suckers. Their cercariae may initiate dermatitis in humans.

Gigantobilharzia: Egg Comparison

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Table 1 presents a comparison of the eggs of *Gigantobilharzia* species (according to Aldhoun and Horne 2014).

Gigantobilharzia: Egg Comparison, Table 1

Species	Egg shape	Egg dimensions (µm)
Undetermined	Oval with spine	153.21 ± 9.07 (142.5–170) × 87.14 ± 8.67 (67.5–107.5)
<i>Gigantobilharzia plectropteri</i>	Fusiform	Not mentioned
<i>G. aegypti</i>	Oval	70–92 × 32–40
<i>G. gyrauli</i>	Oval	60×?? (in uterus)
<i>G. huronensis</i>	Oval	93 × 88
<i>G. huttoni</i>	Oval, occasionally with rudimentary spine	90–99 × 61–67
<i>G. lawayi</i>	Oval	94.12 ± 9.38 × 76.23 ± 7.54
<i>G. acotylea</i>	Oval with a spine	92–110 × 62–67
<i>G. elongata</i>	Oval with a spine	37–44 × 45–52
<i>G. melanoidis</i>	Oval with a spine	95.3 (75–112) × 70.5 (58–80)
<i>G. monocotylea</i>	Oval with a spine	130 × 100
<i>G. sturniae</i>	Oval with a spine	84 × 47
<i>G. tantali</i>	Oval with a spine	75 × 48
<i>G. vittensis</i>	Oval with a spine	62×?? (in uterus)
<i>G. adami</i>	Unknown	–
<i>G. ardeolae</i>	Unknown	–
<i>G. egreta</i>	Unknown	–
<i>G. mazuriana</i>	Unknown	–
<i>G. nettapi</i>	Unknown	–

According to many authors with slightly varying data.

Glucocorticoids

General Information

Glucocorticoids are lipophilic steroid hormones which are synthesized *de novo* in the cortex of the adrenal organ. They exert a variety of different effects on the host itself, e.g., on the water balance and regulation of ion content, growth and differentiation processes, and on the immune system. It is therefore difficult to define the mechanism of action of glucocorticoids on parasites and to clarify whether these are direct or indirect effects.

Pathology

It is impossible as yet to give a coherent picture of the influence of glucocorticoids on parasites and vice versa. In some instances there are even contradictory results: for example, corticosteroid hormones can increase or decrease the infection rate within the same systematic group. One possible explanation is the finding that the ► [fecundity](#) of adult parasitic ► [nematodes](#) increases at lower glucocorticoid levels but decreases at higher concentrations of hormone.

Clinical Relevance

Due to their immunosuppressive action glucocorticoids usually have a deleterious effect on the host and may lead to higher degrees or to prolonged parasitemia. Glucocorticoid therapy may therefore be risky, especially, e.g., if a patient suffers from cerebral malaria.

Glucose-6-Phosphate Dehydrogenase Deficiency (G6PD)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Glucose-6-phosphate dehydrogenase deficiency is the most common human disease of

metabolism. About 400 million humans (black people and people around the Mediterranean Sea) suffer worldwide from this X-chromosome recessively transmitted disease, which leads to a chronic hemolytic anemia and can be initiated, e.g., by sulfonamides and other oxidatively acting substances. With respect to severe malaria, G6PD of type A is thought to reduce the risk of infection for about 50 % in the cases of heterozygous girls and hemizygotous boys.

Surface Coat

Glycolysis

Metabolic process to use glucose, ► [energy metabolism](#).

Glycosomes

These ► [microbodies](#) are specific organelles of kinetoplastic ► [Trypanosomatidae](#). They are ovoid and membrane-bound, appear electron-dense and reach about 0.25 µm in diameter (► [Trypanosoma](#)/Fig. 5). They are rather numerous and contain seven glycolytic enzymes, which in other cells normally occur in the ► [cytoplasm](#). In trypanosomes, however, this energy-delivering process of degrading sugar proceeds exclusively in these organelles, which thus play an important role in metabolic compartmentation. The bloodstream forms (i.e., trypomastigote stages) degrade glucose into pyruvate, which is finally excreted. During this process they need 50–100 % of their dry-weight per hour. Since they are not able to store any polysaccharide internally, they have to take up glucose constantly. If this is not possible (e.g., in cultures), they will die. Therefore these glycosomes are extremely important for the survival of trypanosomes in the bloodstream of their hosts, and thus they have become targets for drug development. *T. cruzi* is an exception and may survive several days without the presence of glucose. This may be due to the activation of the proteins within so-called ► [reservosomes](#) and/or due to the initiation of the respiratory chain-elements, which are present in the blood stages

of *T. cruzi*. Several authors found hints that the glycosomes are evolutionarily related to ► [peroxisomes](#), which are absent in trypanosomes (► [Energy Metabolism](#)).

Glycosylphosphatidylinositols

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

P. Köhler

Glycosylphosphatidylinositols (GPIs) are a family of glycolipids that are widespread in nature implying an important biological role. The major function of these molecules is to anchor proteins to ► [cell membrane](#) surfaces. Parasite GPI anchors may also serve specific roles in modulating the host immune response to infection, in membrane signaling, protein targeting, and intracellular trafficking. The anchored proteins are also functionally diverse and include hydrolytic

enzymes, adhesion molecules, complement regulatory proteins, receptors, and surface coat proteins. The occurrence of GPI anchors is particularly abundant in protozoan parasites, where they serve as the predominant mechanism for integrating glycoproteins and phosphosaccharides into membrane lipid bilayers. Examples are the variant surface glycoproteins (VSGs) of African trypanosomes, which have played a major role in the discovery of ► [GPI](#) membrane anchors, the ► [promastigote surface protease](#) of *Leishmania* spp., the merozoite surface proteins of *Plasmodium falciparum*, and the surface antigens of *Toxoplasma gondii* tachyzoites. In higher eukaryotes, GPI-anchored proteins constitute only a minor proportion of cell surface proteins. GPI anchors are composed of a common core structure of phosphatidylinositol (PI), a mannose-containing glycan chain, and ethanolamine phosphate, which is linked to the C-terminal end of the protein (Fig. 1). The alkyl or acyl chains of the phospholipid provide the attachment of the protein to the membrane from which they can be released by PI-specific phospholipases. The core structure of the GPI is conserved, but marked differences are found in the side chains attached to the core glycolipid. Heterogeneity also exists in

Glycosylphosphatidylinositols, Fig. 1 Protein GPI anchor structure of the *Trypanosoma brucei* variant surface glycoprotein. ● Galactose; ○ mannose; ■ glucosamine; hexagonal ring structure, inositol; P phosphate

Glycosylphosphatidylinositols, Fig. 2 Structures of lipophosphoglycan (LPG) and glycosylphosphatidylinositols (GIPLs) of *Leishmania* spp. (a) LPG of *L. major* promastigote; (b) GIPL of *L. donovani* amastigote;

(c) GIPL of *L. major* promastigote. P phosphate; ○ mannose; ■ glucosamine; ● galactose; ⬡ galactofuranose; hexagonal ring structure, inositol; ▲ glucose

the lipid composition. In *Trypanosoma brucei*, the VSG anchor of bloodstream forms contains exclusively dimyristoyl-PI, while the anchor of the procyclic acidic repetitive protein (PARP) of the insect stage contains 1-stearoyl-PI and is palmitoylated on the inositol. The lipid moiety of *trans*-sialidase of metacyclic *T. cruzi* is a ceramide. The ► [GPI anchor](#) is synthesized in the endoplasmic reticulum by the sequential glycosylation of the PI followed by the addition of ethanolamine phosphate. GPI anchoring proceeds via a transamidation reaction, in which the GPI moiety is attached to the protein via an amide linkage between the GPI ethanolamine and the protein's C-terminal amino acid. GPIs and GPI-related glycolipids of protozoan parasites contribute to a protective ► [glycocalyx](#) formed over the

plasma membrane, such as glycosylinositolphospholipids (GIPLs) of mammalian and insect stage *Leishmania* and the PARP of *T. brucei*. The GPI anchor of the latter protein is heavily substituted with galactose, *N*-acetylglucosamine, and sialic acid.

GPIs are also found in ► [protozoa](#) as mature surface glycolipids which are not linked to protein, such as the lipophosphoglycan (LPG) and GIPLs of leishmanial parasites. These structures have no analogs in higher organisms and appear to represent recent evolutionary adaptations to a parasitic mode of life. GIPLs are structurally closely related to the phosphosaccharide core PI region of LPG (Fig. 2) and form a dense surface ► [glycocalyx](#) above the plasma membrane of about ten million copies in both ► [amastigotes](#)

and promastigotes of *Leishmania* spp. They consist of small mannose- and other hexose-containing glycans that are glycosidically linked to alkylated or alkylated-and-acylated PI. The detailed structure of the GIPLs varies among different leishmanial species and developmental stages of the same species. GIPLs have been suggested to play critical roles in *Leishmania* amastigote survival and virulence.

Glyoxisomes

► **Microbodies** that process lipids for energy production, mainly in plants. However, they have also been described in protozoans such as *Euglena gracilis* and *Tetrahymena pyriformis*, indicating a wider range of adaptations.

Name

Greek: *gnathos* = jaw; *bdella* = leech.

This term describes an order of ► **leeches**. The different species of this family are characterized by jaws provided with sharp teeth and by the fact that they may reach a species-specific length of up to 25 cm. An exception is the so-called horse leech

► *Haemopsis sanguisuga*, which in contrast to its species name (= blood sucking) does not suck blood but engorges other annelid worms. All Gnathostomidae possess five pairs of eyes, and their closed blood vessel system contains reddish blood. Host finding occurs with the help of different sensilla. At first these leeches note the waves that are produced by swimming movements of (mostly warm blooded) hosts. When the leeches come close to their prey, their chemosensillae help to find the direct way and the leeches attach with the help of their anterior sucker, which surrounds the mouth and the three jaws with numerous fine teeth at their upper cutting sites. See ► *Hirudo medicinalis*.

In order to avoid any blocking of the feeding system by blood coagulation, the blood-sucking species inject besides anesthetic compounds also anticoagulants (e.g., hirudin), which keep the wound bleeding, even when the worm has already left the host. Today this hirudin is produced with the help of molecular biological methods, and thus it is no longer needed to collect worms in nature, as it was the case around 1900, when, e.g., in France and Germany several millions of leeches were used per year. The sterile laboratory production of hirudin also excludes the transmission of agents of diseases, which was possible when using living leeches. Nehili et al. (1994) had shown that inside the intestine of *Hirudo medicinalis* several parasites and bacteria are stored and remain infectious for several months. This seems important, since leeches were able to starve for months up to years and could then transmit the agents of diseases. But in case of feeding most of the Gnathobdellidae may ingest blood in a range of 10–15 fold of their own body weight.

Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Greek: *gnathos* = jaw; *soma* = body.

Body region of mites and ticks that bears the mouthparts.

Gnathostoma Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *gnathos* = jaw; *stoma* = mouth;
hispidus = thorny; *dolor* = pain *spinosus* =
thorny, with little teeth.

Geographic Distributions/Epidemiology

- (a) *G. spinigerum*: hosts are cats, dogs, humans in Asia, America, Africa: infected tourists in Europe; ♂ = 10–30 mm; ♀ = ~50 mm.
- (b) *G. hispidum*: hosts are pigs, occasionally numerous cases in Europe and Asia. ♂ = 20 mm; ♀ = 25 mm.
- (c) *G. doloresi*: hosts are pigs (occasionally humans) in the Philippines, India and Asia; ♂ = 20–23 mm; ♀ = 29.34 mm.

Morphology/Life Cycle

These ► [nematodes](#) belong to the order Spirurida, live in the intestinal tracts of their final hosts, and reach maturity there (Fig. 1). Humans are accidental hosts; fish, copepods, and some other hosts may become intermediate hosts. The adult worms have a characteristic shape. They possess an anterior bulbous which is separated from the posterior region by a constriction. Name giving are the parallel rows of hooks which cover the cuticle of the worms (Fig. 2). The hooks on the bulbous are considerably larger than those of the rest of the body. Mostly/often only two thirds of the body are covered by such hooks. The males possess two differently sized spicula. The females produce characteristic eggs, which have a size of $68 \times 37 \mu\text{m}$, appear slightly greenish, and possess at its top site a polar plug (Fig. 3). They were excreted in the two-cell stage. In water the larva 1 is produced inside, which hatches from the egg and becomes ingested by a small crustacean (e.g., *Cyclops*). Inside this intermediate host the larva increases within 1 week, reaches a length of 0.7 mm, and molts to become larva 2. In case this infected *Cyclops* is ingested by a second intermediate host (e.g., frog, reptile, fish) the larva 3 is developed inside its tissues and reaches a size of about 4.5 mm. In rural regions of Asia often 30 % of captured fish are infected. This larva 3 is infectious for the final hosts, where they migrate for 4 weeks in the tissues before they become mature inside cysts in the intestinal tracts (mainly stomach) (Fig. 2b). The females release the eggs (Fig. 3) via a small pore in the cyst. If humans eat infected second intermediate hosts, the larva 3 does not reach maturity but starts a wandering phase of the finally $9\text{--}12 \times 1.2 \text{ mm}$ sized, reddish-white appearing larva (= larva migrans) reaching a speed of 1 cm/h.

Symptoms of disease

- (a) In **humans**: the wandering larvae may introduce the symptoms of the larva migrans (► [creeping eruption](#)), if the larvae 3 migrate through the skin (= gnathostomiasis externa),

Gnathostoma Species, Fig. 1 Life cycle of *Gnathostoma spinigerum* using different types of hosts (a–e) 1 Adults (male 10–30 mm; female up to 50 mm), which are characterized by a spiny anterior bulbous and many body rows of spines, live in the stomach wall of the final hosts (cats) leading to tumorlike growth. 2–4 The eggs ($65\text{--}70 \times 40 \mu\text{m}$) are unembryonated when passed by feces (2). After 1 week of embryonation the first-stage larva (4) hatches in water and swims actively. It remains covered by a thin sheath representing the inner egg shell. 5 The first intermediate host (b) is a cyclopodid copepod, where the L1 penetrates the hemocoel and develops further into a second-stage larva (L2) within 7–10 days. The L2 already has a swollen head bulbous covered with four transverse rows of spines. 6 Fish act as second intermediate hosts when they eat infected copepods. The L2 penetrates

the intestine of its new host and migrates to muscles or connective tissues, where it molts to form the L3 which becomes encapsulated. The L3, measuring about 4 mm, is infective to the final host, where it reaches maturity. However, the encapsulated L3 is also infective to other hosts (d) including humans. 7 If L3 are eaten by other than the final hosts (including man), they wander in that host's tissues without further development; in humans and animals this leads to symptoms of *gnathostomiasis externa* or *interna*, depending on the infected tissues. If humans eat such uncooked paratenic hosts (d), they may become infected but no further development occurs, although the ingested L3 remains infective for final hosts within such paratenic hosts (arrow not drawn to a). In the intestine of humans, worm stages lead to ► [nodule](#) formation (7)

or they lead to internal inflammations, if the worms enter internal organs (= internal gnathostomiasis). In case larvae enter the brain the infection may end fatally. A typical sign of an infection is a high eosinophilia.

- (b) Inside the typical definite **final hosts** the infection with *Gnathostoma* species leads to intestinal disturbances, gastritis, infections, peritonitis (if the wall of the stomach is

passed), or even to death in case of mass infections.

Diagnosis

Microscopic demonstration of the typical eggs (Fig. 3) by help of fecal concentration methods

Gnathostoma Species, Fig. 2 Diagrammatic representation of an adult worm of *Gnathostoma spinigerum* (a) and a section through the wall of the stomach showing one of the typical cysts containing up to eight adult worms (b) B bulbous, C cuticular hook, K wall of the cyst, L lips, LU lumen of the stomach, P pore in the cyst wall

Gnathostoma Species, Fig. 3 Light micrograph of a typical unembryonated egg of *G. spinigerum*

(e.g., ► [flotation](#), ► [M.I.F.C.](#), ► [S.A.F.C.](#)). Since eggs are not excreted continuously, investigation must be repeated.

Infection

Oral infection by ingesting infected raw fish, amphibians, or reptiles.

Prophylaxis: Humans

Should eat only well-done food. **Animals** should not be fed with raw meat or derived products.

Incubation Period

Three to ten days depending on the species.

Prepatent Period

Twenty-eight to thirty-five days in final hosts. In humans there is no reproduction of the worms!

Patency

Eight to twelve months in final hosts. In humans worm larvae live for 2–3 months.

Therapy

See ► [Ascaris](#).

Gnathostoma spinigerum

Classification

Species of ► Nematodes.

Morphology

Adult male worms have a length of 10–30 mm, while females reach up to 50 mm; both are characterized by an anterior bulbus and defined rows of spines (Figs. 1, 2, page 568).

Further species with different numbers of hooklets at the anterior bulbus are:

1. *G. hispidum* (in pigs in Europe and Asia; occasionally in humans). The adults reach a length of 25 mm.
2. *G. doloresi*, which is found in pigs in the Philippines, India, and Asia. The females obtain a length of up to 35 mm. ► Creeping eruption in humans was seen after eating raw fish.
3. *G. nipponicum*; this species lives in groups or single in a hard tumor of the esophagal wall of the weasel in Japan. Adult males are 20–23 long, females 29–34 mm.

***Gnathostoma spinigerum*, Fig. 1** SEM of the anterior end of *Gnathostoma spinigerum* showing the spiny cuticle

***Gnathostoma spinigerum*, Fig. 2** LM of the typical egg of *Gnathostoma spinigerum* being characterized by a single terminal plug

► **Creeping eruption** in humans occurred after eating loaches or various fresh water fish containing larvae.

Life Cycle

Fig. 3 (page 567).

Disease

► **Gnathostomiasis.**

***Gnathostoma spinigerum*, Fig. 3** Life cycle of *Gnathostoma spinigerum* using different types of hosts (A–E). 1 Adults (male 10–30 mm; female up to 50 mm), which are characterized by a spiny anterior bulbous and many body rows of spines, live in the stomach wall of the final hosts (cats) leading to tumorlike growths. 2–4 The eggs ($65\text{--}70 \times 40\text{ }\mu\text{m}$) are unembryonated when passed by feces (2). After 1 week of embryonation the first-stage larva (4) hatches in water and swims actively. It remains covered by a thin sheath representing the inner egg shell. 5 The first intermediate host (B) is a cyclopoid copepod, where the L_1 penetrates the hemocoel and develops further into a second-stage larva (L_2) within 7–10 days. The L_2 already has a swollen head bulbous covered with 4 transverse rows of spines. 6 Fish act as second intermediate hosts when they eat infected copepods. The L_2 penetrates the intestine of its new host and migrates to muscles or connective tissues, where it molts to form the L_3 which becomes encapsulated. The L_3 , measuring about 4 mm, is infective to the final host, where it reaches maturity. However, the encapsulated L_3 is also infective to other hosts (D) including humans (E). 7 If L_3 are eaten by other than the final hosts (including man), they wander in that host's tissues without further development; in humans and animals this leads to symptoms of *gnathostomiasis externa* or *interna*, depending on the infected tissues. If humans eat such uncooked paratenic hosts (D), they may become infected but no further development occurs, although the ingested L_3 remain infective for final hosts within such paratenic hosts (arrow not drawn to A). In the intestine of humans, worm stages lead to nodule formation (7)

Gnathostomiasis

Gnathostomiasis is an aberrant infection of man with larvae of ► *Gnathostoma spinigerum* of felines and dogs. It is acquired from contact with meat of infected intermediate hosts (fish, amphibians, reptiles, birds). The larvae from the intermediate hosts enter human tissue and may migrate slowly through many tissues, giving rise to the intermittent subcutaneous swellings and (very often) to intestinal nodules. The worm is surrounded by an inflammatory reaction with many eosinophils. The larvae are especially destructive when they die in the brain or eye.

Main clinical symptoms: Eosinophilic encephalomyelitis due to wandering larvae in brain, leucocytosis, blood ► *eosinophilia*, intestinal nodules.

Incubation period: 3–7 days.

Prepatent period: There is no reproduction in man.

Patent period: Months.

Diagnosis: Serodiagnostic methods.

Prophylaxis: Avoid eating raw meat or undercooked fish and crabs.

Therapy: Treatment see u.

Gnotobiotic Animals

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes animals that are free of parasites or other agents of diseases and thus can be used for experimental infections.

Golgi Apparatus

Dictyosomes are composed of flat sacs with swollen peripheral regions (► [Endocytosis](#)/Fig. 1B, ► [Merozoite](#)/Fig. 1, ► [Trypanosoma](#)/Fig. 5), from which vesicles are formed. Several dictyosomes together form the Golgi apparatus of a cell. However, many protozoans (e.g., merozoites of coccidians) have only 1 dictyosome which then represents the Golgi apparatus, while other parasites (e.g., *Trichomonas*) include several dictyosomes per cell. These organelles are always situated close to the rER and the two organelles act together as functional units in the production and transport of membrane and in the formation and transport of all types of macromolecular proteins and lipids. The dictyosomes are never covered by ribosomes. The principal function of the Golgi apparatus is the transport of secretions and excretions formed on the rER. These reach the dictyosomes at its cis-side and are transported within ► [vacuoles](#) that are cut off at its periphery (the trans-region). Endocytotic vesicles such as food vacuoles also come into contact with the Golgi apparatus and the rER system at points where they fuse with enzyme-containing vacuoles produced by the Golgi apparatus; this is how digestive enzymes and other products enter the endocytotic vacuoles.

Golgi, Camillo (1844–1926)

Italian anatomist, discoverer of the Golgi apparatus. Winner (1906) of the Nobel Prize (together with Ramon y Cajal).

Golgi-Less Secretory System

In *Giardia* encystation occurs via a unique secretory apparatus, which is not a typical Golgi apparatus, but very probably a primordial Golgi or new secretory system composed of “encystation-specific vesicles” (ESV), the surface of which is covered with clathrin and dynamin.

These ESV's become fragmented and form the cyst wall outside of the cell membrane.

Gongylonematidae

Nematode family of the suborder Spirurina, which is characterized by the fact that the males enrol their posterior end.

From Greek: *spira* = winding, *ura* = tail. *Gongylomema* spp. are found in mammals and birds parasitizing the wall of the esophagus. Their life cycle includes intermediate hosts such as beetles and cockroaches. Related groups are worms of the genus ► [Camallanus](#).

Gordian Worms

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

See ► [Nematomorpha](#).

The name comes from a story belonging to the Greek history. The Phrygian king. Gordios had constructed a wicked knot.

The person that would be able to dissolve the single filaments, should become the Emperor of Asia. Alexander the Great from Macedonia (356–323 before Jesus Christ) solved the task by a single cut with his sword and took over the power. “Cutting a Gordian knot” means today to solve an unsolvable problem by force.

GP 90, GP 35/50 Mucins

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Surface glycoproteins in ► [Trypanosoma cruzi](#), which modulate host penetration processes.

GPELF

Global program to eliminate filariasis.

GPI

Synonyms

Apicomplexa; Glycosylphosphatidylinositol

Granulomatous Amebic Encephalitis (GAE)

Brain

Human brain disease due to infection with free-living amoeba (► *Acanthamoeba castellanii*, ► *Balamuthia mandrillaris*). While *Acanthamoeba*-GAE is mainly found only in immunocompromized persons, GAE due to *Balamuthia* occurs in both immunocompetent and immunocompromized ones. *Balamuthia*-trophozoites reach a size of 12–60 (mean 30) µm. *Acanthamoeba* is smaller (25–40 µm).

Granulomes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *granulum* = grain, granule.
This term describes the aspects of microscopic sections through a parasite stage (e.g., larvae of ► *Toxocara* species, eggs of ► *Schistosoma* species, ► *Paragonimus* species) inside a tissue of

host. The host defense system has surrounded this parasitic stage by, e.g., eosinophilic granulocytes and mostly by layers of collagen, so that these places are clearly differentiated from the healthy tissues of the infected organs. See ► [Pathology](#).

Graphidium

Genus of trichostrongylid stomach worm of rodents and rabbits, e.g., *G. strigosum* (hare); *G. neoplasticum* (rat), up to 2 cm in length.

Grassi, Giovanni Battista (1854–1925)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Giovanni Battista Grassi (Fig. 1) was an Italian physician and zoologist, who became famous by his works especially on malaria transmission. He was apparently the first who described the whole life cycle of *Plasmodium falciparum*, while the Nobel Prize winner ► [Ross](#) was the first to show that undefined *Plasmodium relictum* stages from avians are transmitted by a nondetermined mosquito (he wrote: “grey mosquito with dappled wings”). The initial opinion of the Nobel Prize Committee was to share the prize between Ross and Grassi but later favored Ross and awarded him the Nobel Prize for Medicine or Physiology in the year 1902. Grassi’s work was not fully understood, since he published his results in Italian language, so that apparently the Committee failed to recognize the full importance and accuracy of his work, which ended by clear definitions of the different *Plasmodium* species and in the formulation of the rule, which was later called Grassi’s law: “There is no malaria without *Anopheles* mosquitoes.”

Grassi, Giovanni Battista (1854–1925), Fig. 1 Battista Grassi being honored 30 years after his death by an Italian stamp showing the malaria mosquito

Grassi's Law

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The Italian scientist Giovanni Battista Grassi postulated that there is “no malaria without

presence of ► *Anopheles* mosquitoes.” He was the first to show the full life cycle of *Plasmodium falciparum*, but learnt that not all strains/species of the genus *Anopheles* transmit agents of malaria and proved it by description of zoophilic *Anopheles* species.

Greenbottles

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

English trivial term for the metallic brilliant green-appearing adults of the fly genus *Lucilia*.

Gregarina

Genus of ► *Gregarines*, ► *Chromosomes*.

Gregarines

Joseph Schrével and Isabelle Desportes
Biodiversité et Adaptations des Microorganismes à leur Environnement, Unité Molécules de Communication et d'Adaptation Moléculaire, CP 52, Sorbonne Universités, Muséum National Histoire Naturelle UMR 7245 CNRS/MNHN: MCAM, Paris, France

Introduction

In the mid-twentieth century, the living world was divided in plants and animals and, among eucaryotic unicellular organisms (nucleus surrounded by a double membrane), protophyta and protozoa with affinity respectively vegetal

With the collaboration of Doanh BACCAM

L.Guillou, I.Florent & J.Schrével adapted from Adl et al.,2012

Gregarines, Fig. 1 Simplified phylogenetic tree of the superkingdom Eukaryota showing that the Alveolate clade emerges from a common ancestor and the Gregarine class belongs to the Apicomplexa. The phyla of their hosts

are indicated in *green* for Gregarines and in *red* for other Apicomplexa in the Craniata phylum; *SAR* Stramenopiles, Alveolata, Rhizaria

and animal. The occurrence of plastids involved in photosynthesis differentiated the protophyta from the protozoa. In the *Traité de Zoologie* edited by P.P. Grassé in 1953, Protozoa were represented by amoeba, flagellates, ciliates, and sporozoans. This classification scheme has considerably evolved with the development of the genetics and molecular biology. Using rDNA sequencing of ribosomal 16S and 18S subunits, Carl Woese (1990) could define three groups of living organisms: Archaea, Eubacteria, and Eukaryota. With the generalization of this methodological approach, five super-groups were recognized: SAR Burki et al. 2008, Archaeplastida (Plantae) Adl et al. 2005, Amoebozoa Luhe 1913, Excavata Cavalier-Smith 2002, and Opisthokonta Cavalier-Smith 1987 (Adl et al. 2012) (Fig. 1). The supergroup SAR is an acronym of three groups with a common ancestor: Stramenopiles Patterson 1989 (diatoms, oomycetes, chrysophytes, etc.), Rhizaria Cavalier-Smith 1991 (radiolaria, foraminifera), and the Alveolata Cavalier-Smith 1991 divided in Ciliophora (Ciliates Doflein 1901,

Dinoflagella Bütschli 1885, and Apicomplexa Levine 1971).

The Gregarines belong to the parasitic group Apicomplexa, also represented by Coccidia (*Eimeria*, *Toxoplasma*), Hemosporidia (*Plasmodium*), and Piroplasma (*Babesia*).

Apicomplexa are widespread in nonvertebrates and vertebrates. Most known apicomplexans belong to the genera *Plasmodium* and *Toxoplasma*, respectively, causative agents of malaria and toxoplasmosis.

Gregarines are restricted to nonvertebrate hosts (annelids, crustacea, insects, myriapods, etc.) and urochordates (tunicates). The main characteristic of gregarines is their extracellular development in the digestive tract or coelomic cavities of their hosts. Such locations explain the large sizes and the varied shapes and motilities displayed by these extracellular parasites during the vegetative phase of their life cycle (Desportes and Schrével 2013). The pairing (syzygy) of mature stages (gamonts) at the sexual phase of development (gamogony) is another consequence of the extracellular

Gregarines,

Fig. 2 Diagram of a zoite, the infectious stage of all Apicomplexa species. *IMC* inner membrane complex, *RER* rough endoplasmic reticulum

development. Indeed it results in the synchronous production of an equal number of gametes by male and female gamonts. The gamonts of the other Apicomplexa (Coccidia, Hemosporidia) do not pair and their evolution is quite different. The production of microgametes by male gamonts, and only one macrogamete by female gamonts, appears therefore related with the solitary evolution of the intracellular or epicellular (*Cryptosporidium*) gamonts.

The Zoite: The Infective Stage of Gregarines and Other Apicomplexa

In gregarines as in all other Apicomplexa, the infective stage is the zoite, a polarized cell, characterized by the occurrence of an apical complex (Fig. 2). The apical complex is an assembly of specific organelles including club-shaped rhoptries, filament-like micronemes, dense granules, polar rings, and in gregarines and coccidia, the conoid, a truncated cone consisting of spirally

arranged microtubules. The cell surface of the zoites consists of the plasma membrane and an inner membrane complex (IMC) corresponding to a flattened vesicle. This alveolar cortex is a fundamental characteristic of the Alveolata Cavalier-Smith 1991. The zoites disseminated by spores ensuring host-to-host transmission are named sporozoites. They are designated by merozoites or schizonts when they are generated by asexual multiplication (schizogony) ensuring cell-to-cell transmission in the host. Cell-to-cell transmission, involved in the invasion of the host by the merozoites, is a cause of pathogenicity due to the destruction of infected cells. The molecular composition of the zoites is widely investigated in order to identify therapeutic or vaccinal targets against apicomplexans involved in human and veterinary pathologies (malaria, toxoplasmosis, coccidiosis, or piroplasmosis). Such studies are not performed in these parasites as they have no economical consequences. However they could provide most interesting informations on the phylogeny of these parasites.

Life Cycles

As in all apicomplexan, the life-cycle of gregarines consists of a vegetative trophic phase followed by a sexual phase characterized by the pairing of male and female gamonts the so-called syzygy, and their encystment within a common cyst wall under which gamogony then sporogony take place. The term of this sexual phase is the production of zoites ensuring the host-to-host transmission of the parasite.

The life-cycle of *Lecudina tuzetae* Schr vel 1964, an intestinal parasite of the polychaete *Neanthes (Nereis) diversicolor*, represents an example for the Eugregarines (Fig. 3).

During the polychete feeding, spores of the gregarine are ingested and after their dehiscence inside the intestinal lumen the sporozoites (eight per spore) are released. They migrate inside the intestinal epithelium where they start their vegetative growth giving the trophozoite stage. The trophozoites move in the intestinal lumen where they are attached to epithelial cell via a mucron corresponding to the anterior part of the cell. At maturity, trophozoites detach from the intestinal epithelium and initiate the syzygy, a specific pairing between two complementary haploid sexual cells called gamonts. After this syzygy, characteristic of gregarines among Apicomplexa, both gamonts, respectively, the male and the female, secrete a common cyst wall giving a spherical cyst designated as gametocyst. The cysts are released outside the polychaete in their feces. In each gamont, a series of nuclear divisions without cytokinesis (progamic mitosis). Then a cellularization around each nucleus provides about 1,000 of male and the same number of female gametes. This gamogony (about 20 h at 20 °C) produces piriform male flagellate gametes and spherical female aflagellate gametes. The mixing of the gametes, the so-called gamete dance, correspond to the fertilization step (few hours) and the thousand of diploid zygotes. The sporogony starts with the secretion of a cyst wall under which a meiotic division followed by a mitosis generate eight fusiform sporozoites inside one spore. Sometimes to differentiate the cyst during the gamogony the

term of gametocyst is used, and the term of sporokyst during the sporogony.

The extracellular life-cycles characteristic of the eugregarines living in the intestine or coelom of the hosts differentiates an attachment device after the fixation of the sporozoite to the host cell. When it consists of the epimerite as in *Stylocephalus* gregarines, the anchoring structure differentiated into the host cell above the attached sporozoite, and the trophozoite growth is characterized by the distribution of cytoplasmic contents in two parts: the anterior protomerite and the posterior deutomerite. The accumulation and storage of polysaccharides (amylopectin granules) contributes to the individualization of the deutomerite. A transversal septum consisting of a fibrillar material completes the separation of the so-formed deutomerite from the protomerite. Septate trophozoites are observed in a diversity of gregarine families including the Stylocephalidae. As observed in *Stylocephalus* (Fig. 4) the different steps of the life-cycle are similar to those of *Lecudina*.

A second type of life-cycle is characterized by the presence of an asexual phase of multiplication, the schizogony (or merogony), during the vegetative growth phase as in Archigregarines and Neogregarines.

The Archigregarines are intestinal parasites of many Polychaeta, Sipunculida, and some Hemichordata. The most characteristic belong to the family Selenidiidae Brasil 1907.

Their life-cycles (Fig. 5) differ from the Eugregarines in four major aspects:

- The trophozoites contain specific organelles of the zoites: conoid, many rhoptries, and micronemes in the anterior part of the cell. Their cortex organization exhibit sub-microtubular network quite different of the longitudinal folds of many Eugregarines. This cortex organization explains differences with pendular or rolling motility quite different of the gliding or peristaltic motility of many Eugregarines.
- The schizogony is observed during the vegetative growth phase of Selenidiidae.

Gregarines, Fig. 3 Life cycle of *Lecudina tuzetae* Schr vel 1964, an intestinal parasite of the polychaete *Neanthes (Nereis) diversicolor*. 1 sporozoite; 2 trophozoite inserted in the intestinal epithelium of the worm; 3 syzygy; 4 gamont encystment; 5 gamonts with nuclear divisions without cytokinesis in each gamont; 6 gametocyst after cellularization of male and female gametes; 7 flagellate male and spherical female gametes and fertilization producing zygotes; 8 sporoblasts inside the cyst; 9–12 meiosis and a mitosis in each sporoblast produce eight sporozoites. The yellow color corresponds to the vegetative phase inside the host, the blue to the gamogony and the green to the sporogony (From Schr vel 1969)

- During the sexual phase the nuclear multiplications begin at the syzygy before encystment and the colonization of the cytoplasm gamont nuclei.
- The sporogony produces usually four sporozoites per spore.

of small gamonts resulting from the schizogony process.

Diversity of the Morphology and Cell Biology of the Trophozoites

All these characters illustrate the specific position of the Archigregarines among the Gregarines as they represent “hypersporozoites.”

In Neogregarines, the schizogony is a secondary acquisition (Grass  1933). Most of these gregarines are located in small cavities of insects (malpighian tubules, fat body) and more rarely in intestine. Developmental stages are small sized and the gamonts generate low number of gametes (Fig. 6). However the productivity of the sexual phase is maintained due to the high number

The extracellular growth of the gregarines during the vegetative phase of their life cycle results in the different sizes, shapes, and motilities of the trophozoites (Desportes and Schr vel 2013). Examples of the morphological diversity are presented in Fig. 7.

The trophozoites are segmented in three compartments in terrestrial gregarines designated Tricystidae with a septum between the deutomerite and the protomerite and the anterior segment, called epimerite, inserted in the host

Gregarines, Fig. 4 Life cycle of the eugregarine *Stylocephalus* sp. parasite of beetles (Tenebrionidae). 1 sporozoite, 2–5 trophic phase: 2 young trophozoite attached to host gut wall, 3 older trophozoite free in the gut lumen, 4 mature gamont, 5 pairing of gamonts (syzygy), 6–8 gamogony: 6 encysted gamonts, 7 nuclear gamogonic divisions, 8 cyst containing male and female gametes, 9–10 sporulation, 9 rupture of the cyst wall and releasing of monete chains of spores, 10 mature spore containing eight sporozoites

tissue (Fig. 7 (6)). In many trophozoites of gregarines parasites of Annelida, the compartmentation is not observed (Fig. 7 (1)) except for the Dicystidae where a clear peripheral region (ectoplasm) and a granular internal region (endoplasm) without a septum are clearly identified as in *Lecudina* (Fig. 7 (2)). The nucleus is located inside the deutomerite or in the endoplasm, among the amylopectin granules, a storage polysaccharide with glucose residues. The sizes of the gregarines are in large scale and they can reach several millimeters as observed in the coelomic *Urospora longissima* parasite of *Dodecaeria*

(Fig. 7 (4)), up to 20 mm in the intestinal *Porospora gigantea* in lobsters.

Different types of motility are also observed. For instance, pendular or rolling movements are displayed by the archigregarine *Selenidium* (Fig. 7 (1)), and gliding movements by the eugregarines *Lecudina* (Fig. 7 (2)) and *Geneiorhynchus* (Fig. 7 (6)). A peristaltic motility occurs in *Urospora* (Fig. 7 (4–5)). Two types of movements are observed in the life-cycle of *Diplauxis*: pendular at the beginning of the vegetative phase then peristaltic at the end of this phase (Prensier et al. 2008).

Gregarines, Fig. 5 Life cycle of the Archigregarine *Selenidium pendula*, Giard, 1884, an intestinal parasite of the polychaete *Scolecopsis (Nerine) squamata*. 1 sporozoite; 2 trophozoite; 3 caudal syzygy; 4 further development of syzygy, showing the nuclear transformations before encystment; 5 young gametocyst; 6 gametocyst at the end of gametogenesis; 7 spherical female gamete; 8 piriform male gamete; 9 fertilization and formation of zygote; 10 sporoblast (two nuclei); 11 sporoblast (four nuclei); 12 spore with four sporozoites. Dashed lines between stages 1 and 2 correspond to the position of the agamic schizogony phase observed in several other *Selenidium* species (From Schr  vel 1971)

Cell and Molecular Organization of the Cortex of Trophozoites: The Epicyte

The cell surfaces of gregarines are diverse and useful for classification. Archigregarines have large longitudinal folds supported by a network of subpellicular microtubules. Eugregarines with intestine-inhabiting trophozoites possess numerous narrow longitudinal folds. Eugregarines with coelomic trophozoites exhibit a high degree of variation in their cell surfaces. The longitudinal folds are absent or modified while the coelomic location is associated with modifications such as hair-like structures (cytopili) in *Diplauxis*, rosette-like structures at the surface of *Lithocystis foliacea*, and irregularly shaped swellings at the surface of *Pterospora schizosoma*. A fusion of the plasma membrane is observed at the tip of the folds of *Monocystis*.

Neogregarines at their intracellular stages are devoid of folds.

When viewed by conventional transmission electron microscopy (TEM) a unique feature of all these types of cell surface is the presence of two additional membranes lying under the plasma membrane, now designated as inner membrane complex (IMC). This three-layered cortical membrane pattern in gregarines was first seen in *Selenidium hollandei* (Vivier and Schr  vel 1964). This membrane pattern occurs in all apicomplexa trophozoite and zoite stages (Vivier et al. 1970).

Cell Cortex of Archigregarines: The Three Cortical Membranes and the Subpellicular Microtubule Network of the Selenidiidae

The three cortical membranes and the subpellicular microtubule network were clearly

Gregarines, Fig. 6 Life cycle of *Schizocystis gregarinoides* in the intestine of larvae of a diptera: *Ceratopogon solstitialis*. 1–5 Schizogony consisting of the transformation of the sporozoite into multinucleate schizonts. Stages 2, 3, 4 are attached by the swollen apical end to the intestinal epithelium, 1 sporozoite, 2 small binucleate schizont, 3 multinucleate schizont, 4 elongate schizont (13–30 μm) and an ovoid schizont free in the lumen, 5 fragmentation of a large schizont (400 μm) into uninucleate schizozoites. Each schizozoite gives rise to a new generation of multinucleate schizonts. 6 After a series of schizogonic cycles, uninucleate schizozoites enlarge and transform into gamonts. 7 Pairing of gamonts, 8–10

Gamogony, 8 encysted gamonts. The evolution of the gametocyst (diameter varying from 16 to 32 μm , average size: 25 $\times$ 20 μm) is similar to that of eugregarines. 9 Nuclear gamogonic divisions, 10 the male gamont give rise to pear-shaped gametes (5–7 μm) with an apical rostrum and a caudal flagellum (1/15–20 μm). Likewise female gamonts produce spherical gametes (5 μm), 11 gametes of each sex fuse to give a zygote, 12 cyst with sporoblasts, 13 spore (8 $\times$ 4 μm) containing, eight sporozoites. Gametes, zygotes, and spores are scattered between the cyst wall and the central part occupied by the cytoplasmic residuum (From Léger 1909)

demonstrated in *Selenidium hollandi* trophozoite and generalize to all Selenidiidae and Archigregarines (Vivier and Schrével 1964, 1966; Schrével 1970, 1971). The cell surface of the Selenidiidae exhibits large folds separated by grooves that characterize the epicyte. In

gregarines, the epicyte defined the cell surface morphology with the corresponding cortical membranes and cytoskeleton.

Viewed by scanning electron microscopy (SEM) or in cross section by transmission electron microscopy (TEM), the epicyte of *S. hollandi* has

Gregarines, Fig. 7 Gallery of different gregarines during their vegetative growth phase, also called trophozoites. 1 *Selenidium*. 2–3 *Lecudina tuzetae* in light microscopy (2) and in scanning electron microscopy (SEM) (3); note the median dilations in some folds. 4–5 *Urospora longissima* a coelomic gregarine of the Polychaete *Dodecaceria*

observed through the tegument in macrophotography (4) and in DIC microscopy (5). 6 Drawing of *Geneiorhynchus* an intestinal parasite of dragonflies with the three segments, the deutomerite (*d*) containing the nucleus (*N*), the protomerite (*p*), and the epimerite (*e*) (Collection des Protistes du MNHN)

eight large longitudinal folds or bulges on each face (Fig. 8 (1–2)). The number of folds vary among the *Selenidium* species and correspond to the numerous descriptions of the striations observed by light microscopy. Under the plasma membrane and IMC, sets of regularly spaced subpellicular microtubules run parallel with each other along the longitudinal axis of the trophozoite (Fig. 8 (3)). These microtubules are arranged in two main layers in *S. hollandei*: the first is complete with about 20–30 microtubules per fold, while the second is rather incomplete with a wide

space between them (Fig. 8 (7)). In the surface grooves of Selenidiidae trophozoites, and only in this region, different types of ectoplasmic organelles exist in connection with the cortical cell membranes: (i) vacuoles containing concentric membranes (“pseudomyelinic structures”), connected to the IMC by a short peduncle (Fig. 8 (4)); (ii) vesicles opening exteriorly by a short duct in continuity with the plasma membrane and surrounded by a dense ring from the IMC (Fig. 8 (5)), and (iii) bundles of ovoid, electron-dense droplets, facing a point in the envelope where the

Gregarines, Fig. 8 Cortex of the Archigregarine *Selenidium hollandei*, an intestinal parasite of the polychaete *Sabellaria alveolata*. 1 Scanning electron

microscopy (SEM) of the cell surface with bulges (B) and grooves (S). 2 Transverse section of the cell; mitochondria (m), Golgi apparatus (g), intra-endoplasmic reticulum

IMC is interrupted (Fig. 8 (6)). The functions of these various surface-related organelles may represent sites for exchange with the environment.

This subpellicular microtubule network is characteristic of Selenidiidae and Archigregarines (Fig. 8 (7)) (Schr  vel and Philippe 1993).

Model of Cell Surface Organization in Eugregarines: *Gregarina blaberae*

During the vegetative phase of the *G. blaberae* life-cycle an intestinal parasite of the *Blaberus craniifer* cockroach (Fig. 9 (1)), the cell surface of the trophozoite exhibits numerous longitudinal folds, defining the shape of the cell, and disposed as generating lines along the surface of a cylinder (Fig. 9 (2–3)). The density and dimensions of the folds depend on: (1) the degree of development of the trophozoite; (2) the anterior-posterior gradient of the cell surface; and (3) the sexual differentiation of the gregarine. On a mature trophozoite, numerous folds are observed, those of the protomerite being larger (Fig. 9 (2)) than the folds of the deutomerite (Fig. 9 (3)).

Some folds are straight, some undulate slightly. The frequency of folds is about seven to eight per 1 μm of the length of gregarine circumference. This represents a total of about 1,000–1,800 folds on the surface of a trophozoite. These folds run along the whole length of the protomerite and deutomerite (about 500 μm) but are absent from the epimerite, the anterior segment of the trophozoite involved in cell fixation and nutrition.

Structure of the Folds

With TEM imaging, the cross section of each fold shows the characteristic organization of a Eugregarine trophozoite (Fig. 9 (5)). In the three-membrane cortical layer, the IMC lies at the distance of about 35 nm under the plasma

membrane and forms a regular envelope. The plasma membrane is covered by a filamentous coat rich in glycoconjugates. In the middle part of the trophozoite, the apex of each fold forms a tubular dilatation with different structures.

1. The 12-nm filaments

These filaments run under the IMC membranes along the longitudinal axis of each fold (Fig. 9 (5)). Their diameter is about 12 nm. Sometimes, they reveal a clear central core. The lateral distance between the 12-nm filaments of *G. blaberae* is 28 nm. In mature trophozoites, there are two types of fold configurations that differ in height and number of 12-nm filaments. Deutomerite folds (middle and posterior parts of the cell) are elongated and about 1–2 μm . They contain 10–12 of the 12 nm-filaments at the apex of each fold. In contrast, protomerite folds (anterior part of the cell) are characterized by their rounded shape, smaller height (about 0.6–0.8 μm), and the presence of about 14–16 apical filaments.

The 12-nm filaments exhibit some properties of intermediate filaments as shown by their insolubility in both nonionic detergent and high ionic strength solutions. If one estimates of the total length of all these 12-nm filaments for a single gregarine, with a mean of about 10 per fold, 1,000–1,800 folds per trophozoite, and a length of 500 μm for a mature gregarine, they represent approximately 6–8 m per gregarine. It can be assumed that these structures play a significant part in cell surface morphogenesis, with a supportive scaffolding function in the folds of these Eugregarines.

2. The apical rippled dense structures

Rippled dense structures (rds) are located between the plasma membrane and the IMC

Gregarines, Fig. 8 (continued) granule (*ig*), amylopectin granule (*am*), and lipid droplet (*ld*). 3 The cortex is composed of the plasma membrane (*PM*) and two cytomembranes corresponding to the inner membrane complex (*IMC*); a clear hexagonal zone (*black arrow*) surrounded each microtubule. 4 Cortical zone with a vacuole containing pseudomyelin structures (*thick arrow*).

The trophozoite with two segments: the anterior protomerite (*p*) and the posterior deutomerite (*d*) containing the nucleus (*n*) are separated by a septum (*s*). 2 SEM image of the transition area between the protomerite and the deutomerite; longitudinal folds (*lf*). 3 SEM of the deutomerite surface. 4 Diagram of the epicytic fold after TEM and freeze fracture; the exoplasmic faces are EFp, EFec, EFic for the plasma membrane, the external IMC membrane and the internal IMC membrane, respectively, the corresponding protoplasmic faces are PFp, PFec, PFic. C, cortical membranes; *f*, 12 nm-filament; *il*, internal lamina; *PM*, plasma membrane; *po*, pore-like structure in the membranes; *rds*, rippled dense structure. 5 TEM of the deutomerite and the newly formed folds (arrowheads) the number of the 12-nm filaments (*f*) and *rds* correlates with the size of the folds; plasma membrane (*PM*), cell coat (*C*) (From Schr vel et al. 1983)

membranes (Fig. 9 (4–5)). Their base sits on the external IMC membrane, and the median plane of each *rds* appears to be located between neighboring 12-nm filaments.

3. The internal lamina

An electron-opaque layer of about 15–30 nm, running under the IMC membranes and linking the bases of the folds is usually

visible in TEM sections of the gregarine cortex (Fig. 9 (4–5)). This structure is called the internal lamina. Careful examination showed that this lamina is also present under the internal IMC. In large protomeritic folds, no links are present between the folds. The internal lamina could provide a scaffolding function between the numerous longitudinal folds.

Sequential steps in the growth of folds are observed in the deutomerite of *G. blaberae* trophozoites, where new folds appear between the older ones (Fig. 9 (5)). Such images can be interpreted as an intususceptive growth process and a way to add deutomeritic folds during the entire growth period of the *G. blaberae* trophozoite. The 12-nm filaments appear first in the dilated tip of each growing fold and their numbers as well as those of rds increase with the heights of the growing folds (Fig. 9 (5)). The spatio-temporal development of the 12-nm filaments and their related rds is not clearly defined, since the folds in the protomerite and the deutomerite are continuous and a reduction in the number of 12-nm filaments from 14–16 to 10–12 is observed from the tip protomerite to the end of the deutomerite.

Diversity of Epicyte Folds in Eugregarines

Many TEM observations showed that the cortex of Eugregarines exhibit an organization similar to that of *G. blaberae*. However, variations in the IMC continuity and in the occurrence of pores contribute to specific differentiation of their epicytes. In some Eugregarines trophozoites, which lack longitudinal folds and whose motility is not of the gliding but of peristaltic type, the epicyte has an unusual organization likely to be related to the extraintestinal location of the parasite. In the Monocystidae, *Monocystis herculea*, a parasite of the *Lumbricus terrestris* oligochaete, a fusion of the plasma membrane is observed at the apex of several longitudinal folds; however the underlying continuous IMC, the 12-nm filaments, and rds are present. The cell surface of the intestinal gregarine *Trichorhynchus pulcher*, parasite of *Scolopendra*, or the coelomic gregarine *Diplauxis hatti* parasite of the *Perinereis pellucida* polychaete are covered by numerous

cytopili (Fig. 11 (3)). The taxonomic importance of the epicyte was also clearly shown for *Lankesteria ascidia*, a parasite of the Tunicates where the epicyte is characterized by regular patterns of parallel rows of small knobs. The most likely importance of the microvilli or cytopili is to increase the cell surface of the gregarine in contact with the host environment.

The nature of the cell surface of Neogregarines is not yet well documented.

Cytoskeleton and Cell Motility

Early in the twentieth century, the relationship between motility of the gregarine trophozoites and cytoskeletal elements was proposed with “myonemes, fibrillar, and/or contractile elements.” Numerous morphological studies have described a variety of filamentous myonemes, but their biochemical and molecular identification is quite recent.

The Molecular Compounds

The first SDS-PAGE analyses and Western blotting indicated presence of actin in *Gregarina garnhami*, *G. blaberae*, and *Lecudina pellucida* trophozoites, but the definitive molecular characterization of actin was performed on *G. polymorpha* trophozoite by Heintzelman (2004). The full sequence of this actin gene, predicts a 41.7 kDa protein and the gene is in single copy. The immunolocalization with heterologous antibodies against actin and specific *G. polymorpha* anti-actin showed labeling in the attachment organelles and the parasite cortex and with the rabbit antibodies against the *G. polymorpha* actin fusion proteins visualized in the cell cortex (Heintzelman 2004).

Heterologous antibodies directed against muscle myosins were able to identify a myosin-like protein in *G. blaberae*; however, Heintzelman and coworkers demonstrated clearly the presence of three myosins in *G. polymorpha*. First, the myosin A (GpMyoA) gene encoding a 93 kDa myosin protein homologous to the *Toxoplasma* and *Plasmodium* myosin A; the second *G. polymorpha* myosin B (GpMyoB), a 96 kDa myosin. These two gregarine myosins belong to the class XIV of myosins, a family limited to the Apicomplexa. More recently, a third myosin, the

G. polymorpha myosin F (GpMyoF) a 222.7 kDa protein, was characterized with a canonical myosin motor domain and multiple WD40 repeats at the C-terminal position (Heintzelman and Mateer 2008). This WD 40 motif designated the Class XII of the myosin family also present in several Apicomplexa (*Plasmodium*, *Toxoplasma*, *Cryptosporidium*) (Foth et al. 2006). By indirect immunofluorescence, GpMyoA was localized to the longitudinal epicytic folds and subjacent rib-like myonemes that gird the parasite cortex. The GpMyoB was exclusively localized to the epicytic folds and the GpMyoF with the annular myonemes which gird the parasite cortex beneath the epicytic folds.

Tubulins and spectrin-like proteins were also identified on *Lecudina* and *Gregarina* using immunofluorescence, SDS-PAGE, and Western blotting. Indications on the presence of nonerythroid spectrins in *G. blaberae*, *L. pellucida*, and *Selenidium pendula* were provided by using polyclonal and monoclonal antibodies to human erythrocyte (β -spectrin) in immunoblotting and immunofluorescence. These spectrin-like proteins, which resolves in the gel as a doublet of Mr 260–240,000, is present in the ghosts of *G. blaberae* but not in cytoplasmic extracts nor in extracts from sexual stages, and therefore is stage-dependent (Ghazali et al. 1989). More studies on gregarines are needed before it can be asserted that the distribution of spectrin-like proteins is consistent with a function of stabilization of the cortex.

Cell Motility of Gregarine Trophozoites

Cell motility in trophozoites depends on mechanico-chemical systems for generating the motile force and on cytoskeletal structures for stabilizing the cell shape that determines the type of motility. However, the motor molecules involved in gregarine motility are rather poorly characterized in contrast to other Apicomplexa (*Toxoplasma*, *Plasmodium*). Several cinematographic illustrations of gregarine motility are, however, available on the website: www.cerimes.education.fr:

- Mouvements chez les Grégarines 1967 J. Schrével (14 mn)

- Gamétogenèse chez la grégarine *Diplauxis hatti* 1977 G. Prensier (7 mn)
- Cell motility and microtubules 1982 S. Goldstein and J. Schrével (23 mn)

Gliding Motility The characteristic gliding movement of *Gregarina* trophozoites (1–10 $\mu\text{m/s}$) is a unidirectional movement without a change in cell shape, with respect to the antero-posterior axis of the cell and with shedding of a mucous trail behind the gliding gregarine (Fig. 10 (1)). One mechanism initially suggested was that the secreted mucus pushed the cell forward passively. If the mucus acts as a lubricant, the mechanism of gliding motility of Eugregarines involves a mechanico-chemical system(s) explaining the undulations of the epicytic folds. Many studies with light, SEM, and TEM microscopy exhibit straight and curved folds with an alternation. The rds/12-nm filaments are observed at the apices of the folds and the undulations are in the lateral part. Several possibilities are suggested to explain these undulations: (i) an actin-myosin system, (ii) a translocator such as a dynein/kinesin-tubulin system, or (iii) a system specific to gregarines. The translocation of concanavalin A beads along the cell surface, in an antero-posterior direction, at rates similar to forward gliding movement indicates that the gregarine generate substantial locomotory forces (King 1981). The clear identification of actin and different myosins in *Gregarina* and *Lecudina* suggest that they are involved in the mechanico-chemical mechanism of Eugregarine gliding. The same interpretation was recently provided by the inhibitory effect of the jasplakinolide (a strong actin stabilizer) and cytochalasin D (inhibitor of actin polymerization) in the gliding of the three intestinal *Gregarina* parasite of the *Tenebrio molitor* coleopteran (Valigurova et al. 2013).

Pendular and Rolling Movements in Selenidiidae Selenidiidae intestinal gregarines of many polychaetes and sipunculids exhibit different types of movements which vary in form and speed. *Selenidium pendula*, the type species, exhibits pendular movements (Fig. 10 (2)), as do the Selenidiidae from the polychaetes, Spionidae.

Gregarines, Fig. 10 Recording sequences of motility in gregarine trophozoites. 1 Gliding of the Eugregarine *Lecudina tuzetae*. 2 Pendular motility of the Archigregarine *Selenidium pendula* from stroboscopic records. In this one pendular beat the time between two

frames is 0.2 s. 3 Rolling motility of the Archigregarine *Selenidium sabellariae*. 4 Peristaltic motility of the coelomic *Urospora longissima*. Note on the left the nucleus with its spheric nucleolus (From 1, 3, 4 www.cerimes.education.fr: Mouvements chez les Grégaires 1967 J. Schrével)

Gregarines, Fig. 11 Cell surface of the coelomic gregarine *Diplauxis hatti*. 1 Growth of the paired gamonts in *Perinereis cultrifera* (light microscopy). Insert: Small paired gregarines (20 µm long) in the first days of the worm life cycle and 6 months later (60–70 µm). 2 Two

years later a fast growth of the gamonts occurs during the *Perinereis* gametogenesis; N, nucleus. 3 TEM section of hair-like structures (microvilli) covering the cell surface (From 1–2 to Prensier et al. 2008; 3 to Vivier and Petitprez 1968)

In contrast, Selenidiidae from the Cirratulidae or Sabellariidae show rolling movements (Fig. 10 (3)). The pendular motility of *S. pendula* exhibits a regular periodicity of about 2–3 s (Fig. 10 (2)) and the propagation waves are generated in the anterior part of the cell (Goldstein and Schrével 1982a). In contrast to *S. pendula*, the motility of the Selenidiidae from Sabellariidae and Sipunculids is more complex. The trophozoites are seen as large tape-like cells that actively and irregularly change conformation by twisting, folding, shrinking, and expanding cell volume (Schrével 1967; Leander 2006). The different speeds of motile movements among the Selenidiidae are probably related to availability of oxygen in their environments.

The regular sets of the subpellicular microtubules under the cortical membranes were investigated to analyze their roles in the rolling movements. Using experiments of depolymerization/repolymerization of MTS on *S. hollandei* trophozoites based in seawater containing 0.6–1.0 M urea, the subpellicular microtubules depolymerized and the rolling motility was stopped. The reversion of the MTS depolymerization was obtained when treated *S. hollandei* returned into normal seawater and the motility was restored. Several cycles of urea incubations could be repeated but it was not possible to demonstrate an active role of MTS in the mechanism of motility or a static cytoskeleton activity in maintaining the cell shape (Schrével et al. 1974).

Peristaltic Motility Strong peristaltic movements occur in the coelomic gregarine *Urospora longissima* and *Lithocystis schneideri*, in syzygy-paired trophozoites of *Pterospora petaloprocti*, as well in some in intestinal gregarines as *Didymophyes gigantea*, a parasite of the scarabaeid beetle *Oryctes nasicornis* larva. Their own peristaltic waves occur about every 2 s, the waves moving backward and forward. During wave propagation, the trophozoites are driven in spiral-like movements. Constriction of the cytoplasm at the level of the nucleus distorts this structure as observed in *Urospora longissima* and the nucleolus can also be compressed by the

peristaltic wave (Fig. 10 (4)). As far as peristaltic motility is concerned, the example of the intestinal gregarine *Platyproteum (Selenidium) vivax* is interesting. The SEM observations in contracted and semi-relaxed states of the *S. vivax* showed the presence of transverse striations and the longitudinal epicytic folds indicating an underlying mechanism for the generation and the co-ordination of the peristaltic movements (Leander 2006).

Diversity in Nutrition: Cell Surface, Mucron, Epimerite

Gregarine trophozoites have a high degree of polarity with an anterior part that is usually specialized for attachment of the parasite to its host cell. However, some gregarine species are not attached and move passively with the movements of the host coelomic liquid, e.g., *Gonospora varia*, *Urospora longissima*, and *Diplauxis hatti* gregarines of polychaete worms and *Lithocystis*, a coelomic parasite of the echinoid *Echinocardium cordatum*. Except such cases, the gregarine trophozoites are attached by anterior structures that consist of a mucron in the Aseptata gregarines including Monocystidae and Dicystidae types and of an epimerite in the Eugregarines of the Tricystidae type. Neogregarine trophozoites are usually intracellular or lie within tissues, with no or a reduced small part (“pseudoeppimerite”) specialized for attachment (see Grassé (1953) for review).

Different modes of feeding are found in Archigregarines and Eugregarines. They include two major types: (1) cell surface nutrition via micropores or epicyte differentiations and (2) myzocytosis via the apical attachment complex.

Cell Surface Nutrition

Surface nutrition via micropores was originally proposed by Warner (1968) with an estimation of 8,000–12,000 pores at the cell surface of a *Rhynchocystis pilosa* trophozoite (140 μ m length). In *D. hatti* gregarines growing freely in the coelom of *Perinereis cultrifera* no micropores were identified. Their cell surface exhibits numerous hair-like microvilli situated over the whole

Gregarines, Fig. 12 Mucron of an Archigregarine. 1 TEM section through the conoid and the anterior region of a *Selenidium hollandei* trophozoite where food vacuoles (fv) are formed through the conoid (Co); IE, intestinal epithelium; m.u., mucron. 2 Diagram of the mucron of a *S. hollandei* trophozoite inserted into the *Sabellaria*

intestinal cell; pv pinocytotic vesicles at the food vacuole periphery; co, conoid; m, mitochondrion; mt, microtubule; PM, plasma membrane; R, rhoptry; v, vacuole. 3 The mucron (mu) of *S. hollandei* induces lytic transformations of the host cell with a gradient of effects (From Schrével 1968)

cell surface except the anterior part of the paired associations (Fig. 11 (1–3)). The presence of microvilli may enable the efficient osmotrophic nutrition required for the fast growth of these gregarines.

Growth of the *Gregarina blaberae* continues even when the trophozoites become detached as well as before and after the host's molting indicating a cell surface nutrition. Different experimental assays on gregarine feeding have been performed using radioactive precursors and the labeling sites probably resulted from permeation pathways in the cortical membranes.

Myzocytosis: Mucrons of Archigregarines and Dicystid Gregarines

Myzocystis (from the greek myzein, meaning “to suck”), also called “cellular vampirism,” is a predatory mode whereby a cell can act on the plasma membrane or the cell wall of a host cell or prey in order to suck out the cytoplasm and digest it. In gregarine sporozoites and Archigregarine mucrons, the area of the conoid at the cell apex serves for the fixation to a host cell and for feeding. In contrast, the mucron of Dicystid Eugregarines, such as *Lecudina*, is represented

by the slightly evaginated cell apex, full of microfilaments and not separated from the rest of the cell body by a septum or membrane.

Mucrons of Archigregarines with a Conoid Structure Derived from the Sporozoite

The role of the sporozoite apex in feeding was first demonstrated in early development stages of *Ascogregarina (Lankesteria) culicis* from *Aedes aegypti* intestine by TEM (Sheffield et al. 1971). Food vacuoles are formed via the conoid, and contain heterogenous pieces of host material and residual compounds indicating a phagocytic process. Numerous dense bodies quite similar to micronemes are present in the anterior part of the sporozoite between the nucleus and the apex.

The characteristic organelles of a sporozoite were also visualized in the mucron of the Archigregarines *Selenidium hollandei* and *S. orientale* with the conoid, food vacuoles, and apical dense organelles (rhoptry and microneme-like structures) (Fig. 12 (1–2)) (Schrével 1968; Simdyanov and Kuvardina 2007). The conoid is a truncated cone about 225 nm high, and the respective apical and distal diameters of about 350 and 515 nm. Large food vacuoles (3 μm

Gregarines, Fig. 13 Mucron of the marine eugregarine *Lecudina*. 1 Immunofluorescence with anti-actin antibody shows a strong labeling of the *L. pellucida* mucron. 2 Modifications of the epithelial cell of the host *Neanthes diversicolor* in contact with the *L. tuzetae* mucron (*mu*). Those host organelles, closer to the mucron, are more heavily transformed than those further away where lipid

droplets (*LD*) and mitochondrion (*m*) are visible; *db*, dense body; *mv*, host cell microvilli. 3 Lytic modifications of the *Perinereis* host cell in contact with the *L. pellucida* mucron appear to correspond to blood coming from the polychaeta (From 1–2 to Ghazali et al. 1989, 3 to Schrével and Vivier 1966)

long) pass throughout the conoid lumen. Several vacuoles are present near the anterior end of the trophozoite with numerous small vesicles at their periphery, similar to micropinocytic vacuoles (Fig. 12 (2)). A gradient of lytic material in the host cell is focused in direction of the mucron (Fig. 12 (3)). In these Archigregarines, the trophozoites can be considered as “Hypersporozoites” where micronemes are very numerous.

Mucrons with Polarized Fibrillar Networks In this type, first seen in *Lecudina pellucida* and *L. tuzetae* trophozoites, the mucron expands to form a junctional area with the host intestinal epithelial cell (Schrével and Vivier 1966). The ectoplasm underlying the mucron is filled with numerous bundles of 6- to 7-nm filaments, situated among cytoplasmic vesicles (Fig. 13 (2)). The 6- to 7-nm filaments, vesicles, and other organelles are oriented along an anterior-posterior axis. Such a cellular organization also occurs in the intestinal *Ascogregarina* (*Lankesteria*) *barreti*, parasite of the mosquito *Aedes triseriatus* (Vavra 1969), in a

Lecudina-like gregarine parasitic in *Cirriiformia* (*Audouinia*) *tentaculata* (Ouassi and Porchet-Henneré 1978). A very strong immunolabeling of actin was obtained in *L. pellucida* mucron with specific antibodies against muscle actin into the area corresponding to the 6–7 nm filaments (Fig. 13 (1)) (Ghazali et al. 1989).

There are two likely functional aspects in the mucron: a mechanical and a nutritional. The mechanical role of adhesion to the host could be mediated by contractile actin-like filaments or by successive “hydraulic” evaginations and retractions of the parasite resulting in a suction process. The efficiency of this sucker system must be high since trophozoites remain attached despite strong movements of the host intestine during the polychaete feeding with the organic matter present in the sand. The nutritional function of the mucron is easily observed in *Lecudina*. For example the lytic modifications of the *Perinereis* host cell, visualized in contact of the *L. pellucida* mucron appear to correspond to blood coming from the polychaete sinus (Fig. 12 (3)).

Gregarines, Fig. 14 1 *Epicavus araeoceri* trophozoite in phase contrast microscopy with the epimerite (e), the protomerite (p), and the deutomerite (d) with the nucleus

(n). 2 TEM photograph of the epimerite with long lamellar structures containing different vesicles (Original data)

Epimerites of Septate Gregarines: Complexity, Diversity of Epimerites Eugregarines of the Tricystid type possess epimerites very diverse in size and shape. The example of the intestinal *Epicavus araeoceri* parasite of the *Aeroce* beetle (Fig. 14 (1)) is an illustration of the cellular complexity. This epimerite is cup-like in shape with numerous internal lamellae arising from the neck-shaped protomerite, also called the diamerite (Fig. 14 (2)). An epimeritic septum with a central conoid-like structure is present between the epimerite proper and its neck-shaped appendage (Ormières and Daumal 1970).

During development of *Gregarina blaberae*, the sporozoite conoid persists for a very short period, and after 3 days a large cytoplasmic connection develops between the epimerite and the deutomerite. Many ampuliform vesicles occur under the plasma membrane of the epimerites during the growth of this tricystid gregarine. Their fusion gives rise to a cortical vacuole in *G. blaberae* (Fig. 15 (1–2)) (Tronchin and Schrèvel 1977). No membranous or fibrous separation develops between the epimerite and the protomerite. The presence and types of cytoplasmic inclusions in the epimerite depend on the species examined. For example, numerous mitochondria are present in contact with the cortical

vesicle under the plasma membrane (Fig. 1). The chronology of the epimerite differentiation in *G. blaberae* agrees with previous descriptions on in the Stylocephalidae (Desportes 1969).

In contrast to the mucrons of the Aseptatorina gregarines, the epimerites of Septatorina gregarines do not exhibit very strong lytic effects on their host cells. The minimal effects suggest that nutrient absorption is performed through cortical vesicles by a mechanism based on membrane permeability. Mitochondria near the cortical vesicles may provide the energy for absorption, similarly to the transport processes in vertebrate intestinal cells or kidney epithelial cells.

At the end of the cephaline stage, the epimerite degenerates and or is released. Its separation from the protomerite could result in the constriction of a fibrillar actin-like ring between the epimerite and the protomerite, acting as a sphincter, stopping cytoplasmic flow outside of the epimerite during its breakdown. Another possibility in *G. polymorpha* trophozoite detachment could be based on the epimerite retraction into the protomerite (Valigurova et al. 2009). After the detachment, the sporadine or gamont does not form a new epimerite, and the free unattached gregarines could continue to grow through cell surface nutrition.

Gregarines,

Asexual Multiplication: Schizogony in Archigregarines and Neogregarines

The existence of asexual multiplication (schizogony) occurs during the growth of Archigregarines and Neogregarines.

Schizogony in Archigregarines

The existence of schizogony was clearly illustrated by Brasil (1907), in *Selenidium caulleryi*, an intestinal parasite of the *Protula tubularia* polychaete with the description of coccidioform stages. The sporozoites, released into the intestinal lumen, move through its host's epithelium to reach the basal lamina where they develop into young trophozoites, and after growth the parasite undergoes schizogonic nuclear multiplication producing more than 200 or 300 nuclei. After cellularization, elongate shaped merozoites or schizozoites are well defined (Fig. 16 (1)). A similar intracellular development was reported in *S. metchnikovi* inside the intestinal epithelium of *Glossobalanus minutus* (L  ger and Duboscq 1917), in intestine of the polychaetes *S. mesnili*, parasite of *Myxicola infundibulum* and *S. potamillae*, parasite of *Potamilla reniformis* Ray (1930).

Presence of cysts containing merozoites ("kystes    m  rozoites") was reported in the intestine of the sabellariid polychaete *Sabellaria spinosa* as a parasitic plasmodium ("plasmode parasite") without links to Sporozoa (Dehorne 1931). Later these cysts were shown to be a schizogonic stage of a *Selenidium* (Schr  vel 1971). Histological sections of highly infected *Sabellaria* by *S. hollandei* exhibit intraepithelium cysts (60–70 × 25 µm) near the basal lamina (Fig. 16 (2)) with several dozens of merozoites (Fig. 16 (3)). In TEM, the zoites were clearly identified by the presence of a conoid and specific apical organelles (micronemes, dense bodies) in each merozoite (Fig. 16 (4)). All these examples support the existence of schizogony in *Selenidium* species.

Schizogony in Neogregarines

Schizogony characterizes the development of the neogregarines (Ophryocystidae, Schizocystidae, Caulleryellidae, Syncystidae, Lipotrophidae). The schizogony is usually associated with the poor development of the trophic stages due to their location in narrow cavities of the host tissues. The small-sized gamonts then obtained generate a low number of gametes and spores. The smaller

Gregarines, Fig. 16 Schizogony in *Selenidium* genus. 1 Drawings of asexual schizogony in *S. caulleryi* intestinal parasite of the polychaete *Protula tubularia* with nuclear multiplication giving a syncytium (1) and merozoites after cellularization (2). (2–3) Schizogony in *S. hollandei* the histological sections stained with PAS-Glychemalin show cysts (km) with merozoites in the intestinal epithelium (IE)

of *Sabellaria alveolata*, and numerous sections of *Selenidium* trophozoites (S) in the intestinal lumen. 3 Higher magnification of the cyst from 2. 4 TEM photograph of merozoites, with the characteristic organelles, nucleus (N), amylopectin granules (am), IE, intestinal epithelium (From 1 to Brasil 1907; 2–4 to Schr vel 1971)

gamonts are observed in Lipotrophidae. For instance, only two spores are formed in the cyst in *Mattesia oryzaephili* gregarine of the fat body of a beetle, increasing the number of small-sized gamonts ensures the productivity of the sexual phase. This compensating process is performed by the schizogony.

In *Schizocystis gregarinoides*, an extracellular neogregarine living in the intestine of a Diptera,

L ger (1900) noted that the production of gametes was low (about 100 per gamont) in contrast to that of eugregarines (Fig. 6). These observations indicate that the schizogony is a fundamental characteristic of the apicomplexan life-cycle, even in gregarines. Recent phylogenetic analyses revealed the closeness of eugregarines and neogregarines from insects (Votypka et al. 2009). The schizogony is selected by Coccidia,

Hematozoa, and most neogregarines due to their intracellular development. The lack of schizogony in the majority of eugregarines is likely related with the high production of gametes and spores by the large extracellular gamonts. However, in eugregarines of Gigaductidae family a schizogony is observed due to the effect of the trophozoite location. The sporozoites attach to small apical cells of host's intestinal regenerative crypts and a transient epimerite is differentiated. As the growth of the trophozoites is limited in the cells dividing at the apex of the regenerative crypts, a schizogonic multiplication ensures their dissemination through the successive generations of crypt cells as it also occurs in Gregarinidae of other beetles (Curculionidae) (Théodoridès and Jolivet 1981). Gamonts, gamogony, and sporogony of these gregarines are similar to those of eugregarines, but a low number of large spores are produced in the Gigaductidae cysts.

Syzygy and Gamogony

The gamogony is initiated by the pairing of male and female gamonts. This process is the syzygy that occurs in extracellular spaces such as the gut lumen or coelomic cavities.

Syzygy Process

After leaving the host tissues the cephaline trophozoites transform into gamonts. The mucron is persistent or slightly modified in the gamont of aseptate gregarines. The elimination of epimerite of septate gregarines is an indication of the transformation into a gamont with the proto- and deutomerite segments. Usually the sexual phase starts with the syzygy. In some cases, such as *Diplauxis hatti*, different *Pterospora* living in the coelom of Polychaetes or the Enterocystidae intestinal parasites in mayflies (*Ephemeroptera*), paired associations are observed very early in their life-cycle and they continue their growth during the vegetative phase so the sexual stage really starts with the nuclear multiplication and the cell surface modifications in order to produce a cyst.

The paired cells are species-specific and four major types of syzygy are distinguished:

Four major types of syzygy

- Frontal syzygy. In gregarines such as Actinocephalidae and Lecudinidae the gamonts associate by their anterior end. Frontal syzygy is a consequence of solitary development during the vegetative phase. In *Lecudina platynereidis* the attachment develops a strong fastening system of the “press-button” type (Fig. 17 (3)).
- Caudal syzygy. In some Selenidiidae, such as *Selenidium pendula* or *S. hollandei*, gamonts pair by their posterior ends (Fig. 17 (1–2)).
- Lateral syzygy. In this pattern the gamonts associate side by side as observed in *Lecudina brasili*, *Epicavus araeoceri*, and *Gonospora varia* (Fig. 17 (6)). In *Selenidium sabellariae*, the syzygy is lateral but the two gamonts are oriented in opposite directions (“head to tail”) (Fig. 17 (4–5)), a configuration also referred to as opposite syzygy.
- Caudo-frontal syzygy. In this type of syzygy a gamont is placed behind the other. These gamonts are designated as primate and satellite. The satellite is attached by its anterior end to the posterior end of the primate (Fig. 18 (1)). The associations thus formed are motile and can grow until their encystment. Caudo-frontal syzygy characterizes the development of many gregarines such as the Cephaloidophoridae and the Gregarinidae, respectively, found in crustaceans and insects. According to the gregarine species the caudo-frontal syzygy occurs early, during or at the end of the trophic phase.

The syzygy and encystment are often determined by the host's life-cycle. The different sizes of the cysts are an indication of the host transformations such as in a short-living imago in insects or the status of maturation of the gametes.

Syzygy with Multiple Associations

The association of several gamonts is either occasional or frequent. In hosts highly infested by *Gregarina blaberae*, multiple associations of gamonts occasionally occur, with variations in

Gregarines, Fig. 17 Different types of syzygy. 1–2 Caudal syzygy in the intestinal Archigregarine *Selenidium pendula*. Phase contrast microscopy of live stages. 1 In early syzygy the two gamonts establish a contact between their posterior ends, N, nucleus. 2 Later view of the same syzygy with a large planar contact zone (arrowhead, p) and

the anterior ends (a.e) of the gamonts. 3 Frontal syzygy in the intestinal gregarine *Lecudina platynereidis*. 4–5 Opposite syzygy head to tail of *Selenidium sabellariae*, note the difference of sizes in the two gamonts in (5). 6 Lateral syzygy of the coelomic gregarine *Gonospora varia* (From 1–5 to Schrövel 1970; 6 to Schrövel 1964)

numbers and locations of the satellites. For example, two or three small satellites are attached to the posterior end of a single primitive (Fig. 18 (2–3)) and the following gamonts are satellites. Chains of caudo-frontally attached gamonts characterize the Hirmocystidae, a family of parasites of gryllidae insects and multiple associations are lateral in the Ganymedidae, a family of gregarines parasites of crustaceans. In most cases, the satellites are smaller than the primitive.

In syzygy with supernumerary gamonts, the question of their cellular interactions is not easily defined since the gametocyst is the result of the

evolution of two paired gamonts. The existence of multiple associations of the Y-shaped type or linear type in *G. blaberae* with several satellites attached to a single primitive could represent a recognition process between gamonts before pairing. In *Selenidium pendula* syzygy with three partners, nuclear activation is observed in all three cells indicating sexual signals between them.

Cell Junctions Between Gamonts in Syzygy

Differentiations of the cell surface occur at the junctional zone between paired gamonts. In the Gregarinidae, a septate junction is established

Gregarines, Fig. 18 Syzygy in *Gregarina blaberae* intestinal parasite of the cockroach *Blaberus craniifer*. 1 Caudo-frontal syzygy in phase light microscopy. 2 Multiple associations with two satellites (S_1 , S_2) attached to the

posterior end of the primitive (P) in phase light microscopy. N , nucleus. 3 Triple association observed by scanning electron microscopy. S_1 , S_2 , S_3 , satellites; P , primitive (From Schr  vel and Philippe 1993)

between the closely applied plasma membranes at the tips of the epicytic folds. This septate junction is similar to that ensuring the intercellular cohesion of metazoan cells. The epicytic folds of the junctional area differ in size and in number of the 12-nm filaments. The satellite's epicytic folds are massive with 14–17 filaments, those of the primitive deutomerite are more elongated with 10–12 filaments. In the coelomic gregarine *Diplauxis hatti* the junctional zone of the paired cells exhibit numerous apertures in the two closely apposed plasma membranes where the IMC is lacking (Vivier and Petitprez 1968). The cell communication is shown by the cell-to-cell transfer of the

vesicles through the apertures. These cytoplasmic communications do not suppress the sexual differentiation of the two gamonts since a clear anisogamy is observed with the aflagellate female gametes and the surprising 3 + 0 axonemal flagella in the male gametes.

Gamogony

In gregarines, after the syzygy with two complementary gamonts, the production of the gametes occur within a cyst wall secreted by the paired gamonts (Fig. 19 (1–3)). The differentiation of the

Gregarines, Fig. 19 Early gamogony in *Lecudina* (1–6) and syncytial mitosis of *Grebnickiella gracilis* (7–9). 1–3 Drawings of different stages during the formation of the *Lecudina* gametocyst. 1 Trophozoite; ect, ectoplasm; end, endoplasm; N, nucleus, nu, nucleolus. 2 Lateral syzygy. 3 Gametocyst. 4–5 Immunofluorescence staining of cortical microtubules of *L. tuzetae* during early gametogenesis, detected with anti- α -tubulin antibody and imaged by confocal fluorescence microscopy. 4 The plane of the two

gamonts inside the gametocyst showing the mucron association. 5 Spindles of the first progameic mitosis and the cortical network of microtubules. 6 Gamonts prepared 3–4 h after release from the host and immunostaining with anti- α -tubulin antibody and the corresponding DAPI staining showing the presence of about 16 DNA-containing structures. 7–9 Progameic mitosis in *Grebnickiella gracilis*. 7 Drawings of the different steps of the mitosis: Prophase with two cytoplasmic hemi-spindles focused on MTOC

gametes is initiated by syncytial nuclear divisions in each gamont, followed by a process of cellularization around the newly formed nuclei.

Encystment

As indicated by the spherical shape of the cysts (or gametocysts), the encystment involves morphological changes of the gamonts and the concomitant secretion of cyst wall components. The encystment of the aseptate eugregarines (Monocystidae) living in the coelom or seminal vesicles of earthworms begins with peristaltic movements anteriorly directed. Such movements result in contractions causing the shortening of the posterior part of the gamonts and the concomitant swelling of their apposed anterior parts and flattening of the junctional zone. In Eugregarines, encystment starts with rotational cytoplasmic movements in each gamont giving the spherical shape to the cyst, the so-called gametocyst (Fig. 19 (4)). In *L. tuzetae*, these movements are probably induced by sexual signals, since in syzygies with three partners, the additional gamont also develops rotational cytoplasmic movements similar to the primary pair. Cytoplasmic movements in *L. tuzetae* gamonts are rapid during the first hour and a half and slower for a number of hours (3–4 at 20 °C) after that. During this period, the two gamonts are linked by their mucrons and a cyst wall is built. Light microscopy observations showed that the cyst wall consists of three layers: an internal layer (1 µm), a middle refringent layer 7–10 µm thick, and an outer homogeneous layer 10 µm thick. The internal homogeneous layer appears very different from the fibrillar middle and outer layers and forms a barrier to the environment, keeping out sea-water and sand particles in the case of *L. tuzetae*, for example.

Cytochemical tests on the gametocyst walls of *L. tuzetae* and *Gregarina blaberae*, with PAS and

Alcian blue staining at pH 2.3, have demonstrated the presence of glycoconjugates with cis-glycol and anionic groups but no biochemical data are currently available.

Rotational cytoplasmic movements of the gamonts continue after the formation of the cyst wall. The IMC of the longitudinal folds becomes progressively disrupted. Finally, the cell surface of the gamonts is flattened and reduced to the outer plasma membrane. Concentric arrays of cortical microtubules that encircle the periphery of the sphere are visualized using an anti- α -tubulin antibody immunofluorescence procedure (Fig. 19 (6)). The space between the plasma membrane of the gamonts and the cyst wall is called copularium.

Syncytial Nuclear Divisions

After the encystment, multiple rounds of asynchronous nuclear divisions (progamic mitosis) transform the mononucleate gamonts of eugregarines into a multinucleate syncytium. The progamic mitoses are characterized by the persistence of the nuclear envelope (cryptomitosis). The first progamic mitosis can be visualized by immunofluorescence (Fig. 19 (5)). Because cytokinesis does not take place, multiple nuclear divisions result in numerous syncytial haploid nuclei (Fig. 19 (6)). After several nuclear divisions, α -tubulin immunostaining shows the presence of microtubule-containing structures associated with each DAPI-positive structure corresponding to DNA (Fig. 19 (6)). As some exhibit mitotic spindles and others show microtubule arrays in interphase, these progamic divisions are not synchronized. In *L. tuzetae* rapid mitotic divisions result in the production of about 1,000–2,000 nuclei within a relatively short period (~15 h at 20 °C). In *L. tuzetae* the microtubules of the MTOC (microtubule organizing

Gregarines, Fig. 19 (continued) after their duplication (1). Migration of the two half-spindles in opposite directions to form a complete spindle across the nucleus and attach the chromosomes to the mitotic microtubules (2–3). One nuclear pole at anaphase showing the migration of the chromosomes toward the MTOC, with their kinetochores attached to the microtubules (4–5). 8 TEM photograph of a

centriolar MTOC with a ring of nine microtubules surrounding acentral microtubule and the astral microtubules joining the nuclear envelope. 9 Duplication of the MTOC outside the nuclear envelope (From 1–3 to Schr  vel 1969; 4–6 to Kuriyama et al. 2005; 7–9 to Molon-Noblot and Desportes 1980)

Gregarines, Fig. 20 Syzygy, gametocyst, and sporokyst of the intestinal Archigregarine *Selenidium pendula* in phase contrast microscopy. 1 At late stage of a living syzygy, the secondary nuclei are clearly visible inside the initial primary nucleus. 2–3 Evolution of the same

S. pendula in early gamogony where the nuclei colonize the cytoplasm of each gamont (2) then in sporogony (3) where the sporoblasts are individualized. Note a significant increase in size between the gametocyst and the sporokyst (From Schr  vel 1970)

center) are dispersed in a disc, and in *Grebniackiella gracilis* parasite of centipedes (Myriapoda) a centriolar-like structure (140–180 nm in diameter) is observed. This centriole consists of a cylinder of nine peripheral singlet microtubules and a single axial microtubule (20 nm).

Before nuclear division, the MTOC undergoes duplication as shown in *L. tuzetae* and *G. gracilis* (Fig. 19 (7–9)). The two MTOCs develop close together outside of the nucleus, and their microtubules radiate to form half-spindles that push into the nuclear envelope, forming cup-shaped invaginations (Fig. 19 (7–8)). The two centers then migrate in opposite directions. As the nuclear envelope persists the microtubules of the half-spindles must penetrate the nuclear envelope to connect with the kinetochores on each chromosome (Fig. 19 (8–9)). Other microtubules extend through the nucleus and connect the chromosome to the pole. Such progamic mitotic spindles were observed in *Stylocephalus longicollis* (Desportes 1970), *L. tuzetae* (Kuriyama et al. 2005), and *G. gracilis* (Molon-Noblot and Desportes 1980). The kinetochores appear in *L. tuzetae* and *G. gracilis* as pentalaminated or trilaminated structures similar to those of *Plasmodium b. berghei* (Schr  vel et al. 1977). Interestingly

the chromosomes of *L. tuzetae* are well condensed whereas in *Plasmodium* the chromosomes are uncondensed (except in the microgametogenesis stage).

In contrast to Eugregarines, the first nuclear divisions in Selenidiidae occur at the syzygy stage before the formation of the gametocyst wall (Fig. 20 (1–2)). Newly formed nuclei (20 or more) are gathered in the gamont nucleus (Fig. 20 (1)). After encystment these are spread nuclei into the cytoplasm giving the syncytial form to the two associated gamonts (Fig. 20 (2)).

Cellularization

After successive nuclear divisions, about 1,000 nuclei are produced in each gamont of *Lecudina tuzetae*. The number of gametes depends on the size of the gamonts and for example is higher in *Stylocephalus* and *Diplauxis hatti*. The fission of the cytoplasm around each syncytial progamic nucleus results into cellularization, i.e., fragmentation of the gamonts into gametes. The cellularization is achieved by a budding process at the surface of the gamonts. In female and male gamonts, the nuclei are at the periphery to produce the “perlage” (budding) of the gametes before their release inside the intracyst space called

Gregarines, Fig. 21 Cellularization at the end of the gametogenesis of the coelomic gregarine *Diplauxis hatti*

(1–2) and the intestinal gregarine *Stylocephalus* (3–6) imaged in TEM. 1 Early stage of budding in the *Diplauxis*

copularium (Fig. 21 (1, 3–4)). In the male gamont, a flagellum arises from the centriole (MTOC) at the anterior end of the budding gamete. The flagellum can be more or less developed. Reduced to a short appendice in Monocystidae, the flagellum lengthened to a long tail in other eugregarines such as the Stylocephalidae. The tail involves a reorientation of the flagellum. At first anteriorly directed (Fig. 21 (2, 6)), the flagellum applies laterally to the budding gamete (Fig. 21 (5)) and then is reinserted into the cell body to finally emerge from the posterior end to form the tail with the free flagellum. In *Stylocephalus*, numerous residual compounds (amylopectin granules, lipid droplets, etc.) are concentrated in the cyst center and form the white “pseudocyst.” Another unique feature in the *Stylocephalus* genus is the unconventional budding process producing large sterile motile male gametes (Léger 1904; Desportes 1970).

Gametes and Fertilization

At the end of gametogenesis, the nature of the differences between the male and the female gametes varies, depending on the gregarine genus. By light microscopy, it is not usually easy to detect anisogamy, as the flagellate male gametes and the aflagellate female gametes are very small, for example 3–5 μm in *Gonospora varia* (Fig. 22 (1)). In contrast, a clear anisogamy is observed in *Selenidium pendula* where the male gamete exhibits a long flagellum (Fig. 22 (2)), also detected during fertilization in *S. mesnili* (Fig. 22 (4)). The female gamete and the zygote are spherical but their diameters are different (Fig. 22 (3)). The major differences are observed in the gametes of Dactylophoridae which are parasites of Myriapoda. The male gamont generates thin fusiform microgametes (10 μm in length) with minimal contents (a nucleus, an elongate mitochondrion, and a flagellum) (Fig. 22 (5)). In

contrast, the female gametes are large cylindrical cells (20 $\times$ 4.5 μm) containing classical organelles, amylopectin granules, and lipid droplets (Léger and Duboscq 1909; Molon-Noblot and Desportes 1977). Curiously, the same type of anisogamy occurs in a neogregarine also parasite of myriapods.

Gametogenesis in the *Stylocephalus* Terrestrial Gregarines

Early in the twentieth century, Léger (1904) carried out a remarkable study of gametogenesis in *Stylocephalus*. The budding process called “perlage des gamètes” in *Stylocephalus* occurs 25–30 h after the release of the cysts at 24 °C, or later at lower temperatures. Two categories of male gametes are observed: (i) the pear-shaped male gametes with one flagellum (Fig. 23 (1)), the most abundant, correspond to the fertile male gametes, and (ii) the fusiform male gametes with two flagella are sterile and less numerous. These sterile gametes are longer (up to 35 μm) than the fertile ones (Fig. 23 (4)). The fertilization (“danse des gamètes”) starts with the migration of the male gametes in the female part of the gametocyst. Both types of male gametes, fertile and sterile, are motile. The sterile ones are very active and enter in the female gamont first. The movements of male gametes consist of strong undulating waves.

TEM performed by Desportes (1970) completed the study of Léger (1904). The budding of the female gametes is in agreement with the histological descriptions of Léger (1904). After the last progamic mitosis, the nuclei (about 3–4 μm) migrate near the cell surface, with the MTOC and the radiating aster microtubules in the front. Large lipid droplets and mitochondria are present around the nucleus. Amylopectin granules are not present in the female buds, but stored in the cytoplasmic residuum and will contribute to the

Gregarines, Fig. 21 (continued) female gamont with the nuclei at the periphery. 2 Early budding in the male gamont with the growth of the flagella (*F*) in the space surrounding the gamont. 3–4 Late cellularization of a *Stylocephalus* female gamete with a mitochondrion as a plug (3) and a mature gamete (4) with large lipid droplet and concentric

pattern of endoplasmic reticulum. 5–6 Flagellar development of a fertile male gamete of *Stylocephalus* from a MTOC located in the front of the nucleus (6) and during its tilting (From 1–2 Prensier et al. 2008; 4–6 Desportes 1970)

DIC microscopy of a live male

gamete with a flagellum (f) showing a dilatation (d) flagellum (2) and a spherical female gamete (f.g) and zygote (z) with two nuclei (3). 4 DIC micrograph of fertilization in *S. mesnili* between a spherical female gamete (f.g) and a flagellated male gamete (m.g). 5 Microgamete and macrogamete of *Grebnickiella gracilis* (From 1 to Trégouboff 1918; 2–4 to Schrével 1971, 5 to Léger and Duboscq 1909)

pseudocyst. Before the release of the female gametes, a mitochondrion is positioned like a plug (Fig. 21 (1, 3, 4)).

The *Stylocephalus* fertile gamete exhibit a variability in the number of flagellar axonemal doublets which can be arranged in a 9 + 0 (Fig. 23 (3)) or a 8 + 0 pattern. This variability in axonemal patterns does not seem to affect flagellar motility.

No clear information is available on the structure of the flagellar root (basal body). Another unusual feature of the *Stylocephalus* fertile gamete is the presence of a number of single microtubules that radiate from a region near the MTOC anterior to the nucleus (Fig. 23 (2)). Such a microtubular structure could constitute the scaffold of the rostrum.

Gregarines, Fig. 23 Structure of the fertile (1–3) and sterile (4–6) *Stylocephalus* male gametes. 1 Drawing according to Léger 1904. 2 Diagram of a fertile *S. longicollis* male gamete; F, flagellum; G, Golgi; LD, lipid droplet; Mi, mitochondria; Mt, microtubule; MTOC,

microtubule organizing center; RER, rough endoplasmic reticulum. 3 Cross section of a 9 + 0 flagellar axoneme: the doublets are linked by a bridge between microtubule b of one doublet and to the following a. (4–6) Sterile *Stylocephalus* male gamete. 4 Drawing according to

During the budding of the sterile male gamete, the two flagella begin straight, then pivot in the same way as the single flagellum does in fertile gametes, so that they come to point posteriorly and grow in that direction to finally reach about 35 μm in length (Fig. 23 (5)). One possibility for generating sterile gametes is the duplication of an MTOC without the normal separation and rapid growth of the flagella from the two neighboring MTOCs. A major peculiarity is that the axonemal pattern of one flagellum is 9 + 0 and the other is 8 + 0 (Fig. 23 (6)). The presence of 9 + 0 and 8 + 0 taxonemal patterns in the same cell is a good illustration of the plasticity of the MTOC during the evolution of *Stylocephalus* in a parasitic context. This example could represent an illustration of the concept of “regressive physiological evolution” in microorganisms (André Lwoff 1944).

The fertilization with the formation of zygotes is realized in the copularium around a central white, granular pseudocyst, in about 1 h 30 at 24 °C. The zygotes develop two small sticky “papilles” pointing in opposite directions that are used to join the sporoblasts and to form long chains or rings. The sterile male gametes move actively against the sporoblasts chains but they gradually degenerate, a rather slow process observed as much as 12 h after fertilization (Léger 1904).

Variations of the 9 + 2 Flagellar Patterns in Marine Male Gametes: 6 + 0, and 3 + 0 Axonemes

In male gametes of marine gregarines, one of the most surprising findings was the simplest axonemes with a 6 + 0 pattern in *Lecudina tuzetae* (Schrével and Besse 1975) and more surprising only a 3 + 0 pattern in *Diplauxis hatti* (Prensier et al. 1980).

The cell bodies of *L. tuzetae* male gametes are spheroidal or pear-shaped (about 5–7 μm in diameter) (Fig. 24 (1)). The flagellum runs from the anterior part of the cell for several micrometers

before exiting the body (Fig. 24 (1)). The free flagellum, with a 6+0 axoneme, is about 10 μm long (7–13 μm) (Fig. 24 (2)). The *D. hatti* male gamete is a spherical cell about 4 μm in diameter. The flagellum is about 20 μm long, with a 3 + 0 axonemal pattern. The diameters of these 6 + 0 and 3 + 0 flagella are smaller (*D. hatti*, 0.11–0.13 μm ; *L. tuzetae*, 0.15–0.18 μm) than that of the classical 9 + 2 flagellum, which is about 0.2 μm . The A subfibers of the 6 + 0 axoneme bear arms similar to dynein arms (Fig. 24 (2)), but in the 3 + 0 axoneme such arms are not clearly seen (Fig. 25 (3)) probably because of difficulties in fixation and embedding for TEM.

In TEM, the basal body appears as a cylinder (250 nm in length $\times$ 130–150 nm in diameter), and in cross section as an electron dense ring (Fig. 24 (3)). A short microtubule (20 nm in diameter) is observed in the axis of these basal bodies (Fig. 24 (4)). This pattern is simpler than the nine microtubule triplets of the classic centrosome. The flagellar root of *L. tuzetae* and of *D. hatti* is located in the anterior part of the gamete and the resulting flagellum runs along the nucleus, and in the free flagellar segments no central microtubules are observed (Fig. 24 (1, 5)). The formation of the flagella in male gametes of *L. tuzetae* and *D. hatti* takes place inside the cytoplasm and corresponds to the so-called cytosolic biogenesis (Avidor-Reiss et al. 2004).

Squashed samples of *L. tuzetae* immunostained for α -tubulin exhibit numerous astral microtubule structures in both female and male gametes. In each aster, 10–20 microtubules of about 5 μm length emanate from a focal center (Fig. 26 (1–3)) and they likely correspond to the interphase microtubule clusters located at the nuclear indentation observed in TEM. As this focal point has been immunostained with anti-centrosomal antibodies raised against mammalian γ -tubulin (Fig. 26 (4)), it is considered as microtubule nucleating site (Kuriyama et al. 2005).

Gregarines, Fig. 23 (continued) Léger 1904. 5 In the anterior end of a sterile gamete viewed by TEM, two flagella cross the nucleus (N) through cytoplasmic

channels. 6 Cross section of the free flagellar segment with a 9 + 0 (left) and a 8 + 0 (right) axoneme (From 1, 4 to Léger 1904; 4–6 to Desportes 1970)

Am, amylopectin granule; f, flagellum; intracytoplasmic portion of the flagellum (arrow); ms, vesicles with mucosubstances. 2 Cross section of a free flagellum with the 6 + 0 axonemal pattern. Each doublet is composed of two subfibers (A and B). 3 Longitudinal section of

the flagellar root. 4 Cross section of the flagellar root near the nucleus (N). 5 Longitudinal section of the flagella through two opposite doublets, central microtubules are absent. fm, flagellar membrane; mt, doublet microtubules. 6 Diagram of the male gamete with the 6 + 0 axonemal pattern and the drawings of different cross sections I, II, III (From Schr vel and Besse 1975)

Gregarines, Fig. 25 TEM of the *Diplauxis hatti* 3 + 0 male gamete. 1 The flagellar axoneme (F) runs along the nucleus (N); the two arrows indicate levels of cross sections shown in (2) and (3); amylopectin granules (Am) and lipid droplets (L). 2 Cross section of flagellum within the cell body (arrow 2 in 1); the doublets (d) are surrounded by dense material. 3 Cross section of a free

flagellum (arrow 1 in 1) with three doublets but no central microtubule. The A-subfiber (A) corresponds to the complete microtubule of each doublet. No interconnecting material was observed between the B-subfiber (B) and the A-subfiber (A) of the adjacent doublet in these difficult conditions of fixation for TEM (From Prensier et al. 1980)

G

Gregarines, Fig. 26 Immunofluorescence staining of microtubules and MTOCs in *Lecudina tuzetae* female (1–2) and male (3–4) gamonts. The gamonts collected 20–22 h after their release from the host were squashed before fixation to release the microtubule containing structures. 1–3 Samples stained with anti-α-tubulin antibody.

4 Triple-stained structures derived from the male gametes visualized with anti-α-tubulin (green), anti-γ-tubulin (red) antibodies and DAPI (blue). Both cytoplasmic microtubules and flagellar axonemal microtubules originate from a common site containing γ-tubulin related molecule (s) (From Kuriyama et al. 2005)

Male gametes contain a thicker and longer fiber protruding from the focal center of other, shorter, microtubules (Fig. 26 (3–4)). The fibers correspond to the flagella, and the site where microtubules originate stains with anti- γ -tubulin antibodies indicating that the MTOC in the male gamete also served as a basal body for the flagellum (Fig. 26 (4)).

Despite their unusual axonemal organization, the male gametes of *L. tuzetae* and *D. hatti* are motile. The 6 + 0 of *L. tuzetae* flagellum beat slowly but continuously, without stopping and starting. The beat period is about 2 s (Goldstein and Schr  vel 1982b). The *D. hatti* flagellum, with the 3 + 0 axoneme, beats more rapidly than the 6 + 0 flagellum of *L. tuzetae*, with a frequency of 1.5 Hz. (Pren  sier et al. 1980). The waveform consists of a series of bends that propagate from base to tip, and appear to consist of three-dimensional, approximatively helical bends rather than a series of planar bends in different planes. The sense of the coil is left-handed and the axoneme twists during beating. After fusion of the male and female gametes, the zygotes produced take on an ovoid shape and the flagella of *L. tuzetae* and *D. hatti* zygotes continue to beat for 1 or 2 h before their disappearance (Goldstein and Schr  vel 1982).

Sporogony

Zygote, Meiosis, and Metagamic Mitosis

The zygote is the only diploid stage in gregarines. The nucleus of the zygote undergoes several metagamic mitoses, three in Eugregarines and two in Selenidiidae, producing eight and four sporozoites respectively. The place of meiosis in the gregarine life cycles was established on careful cytological studies by Grell (1940) (Fig. 27 (1–5)). The pachytene stage of the first nuclear division, characteristic of meiosis, was identified in *Stylocephalus longicollis* sporoblasts. Confirmation of meiosis was provided later using TEM by the presence of synaptonemal complexes in the first division of the zygote of *Grebnickiella*

gracilis (Fig. 27 (6)) (Molon-Noblot and Desportes 1977).

In the first postfertilization nuclear division of *L. tuzetae* (Fig. 27 (7)), the microtubules of the spindle are immunolabeled with anti- α -tubulin antibody but also antibodies against the pericentriolar Cep 135 protein. This protein originally identified as a scaffolding compound of the mammalian centrosome indicates the conservation of some centriolar structures of the classical 9 + 0 axonemal flagellum in gregarines (Kuriyama et al. 2005).

Metagamic mitoses are cryptomitoses similar to the progamic mitoses described for gamogony. They are characterized by the persistence of the nuclear envelope and by the presence of condensed chromosomes. The number of spores are usually very high as shown in *Gonospora varia* (Fig. 28 (1–2)). The sporogenesis continues with the differentiation of the sporozoites.

Secretion of the Sporoblast Wall and Cytoplasmic Events

After fertilization, the zygote starts the sporogony process. A thin wall is secreted very early around each zygote. The term sporoblast designates the structure from the zygote to the end of sporozoite biogenesis. When the sporozoites are fully differentiated the terms spores are used. This term spore is preferable to sporocyst or oocysts commonly used to designate this stage. The term of oocyst should be restricted to the coccidian zygote.

Maturation of the sporoblasts of Eugregarines usually takes 2–3 days at 18–20 °C. The young sporoblast with a single nucleus is surrounded by a regular homogenous dense wall with a fuzzy coat. Later, the wall differentiates into a thin layer (endospore) in contact with the sporoblast cell and an exospore layer, externally, often ornamented with spiny or filamentous appendages. In some Eugregarines with homopolar spores, i.e., *Stylocephalus*, discoidal contacts develop between young sporoblasts. Fibrillar junctional material enable the formation of long chains of spores when extruded from the sporokysts (Fig. 28 (2, 4–5)).

Diversity of the Spore Structures of Gregarines and Sporulation

The importance of spores in systematics was clearly shown by Schneider (1875) and Léger (1892). From the diversity of shapes and sizes, about 30 types of spores were characterized with three major types: homopolar, heteropolar, or conrescent.

The name of many genera of gregarines is defined from the spore characteristics: *Urospora*, Schneider; *Gonospora*, Schneider; *Ceratospora*, Léger; and *Acanthospora*, Léger. In addition *Pterospora* is characterized by large expansions of the exospore giving the appearance of wings.

An example to illustrate the importance of spores to define the right systematic position is *Gonospora longissima*, a coelomic gregarine of *Dodecaceria polychaete* (Caullery and Mesnil 1898). Initially described with pyriform spores with a neck pole and a blunt spike, the spores released during the nuptial dance of the worm exhibit a long filament of about 90–100 µm at the pole opposite to the neck (Fig. 27 (3–4)). In consequence, this gregarine is reclassified as *Urospora* (*Gonospora*) *longissima*, Schrével (1965) (Caullery and Mesnil 1898). In Selenidiidae, the spores are uniformly spherical with only four sporozoites (Fig. 29 (3)) but most

Gregarines, Fig. 29 Spores, sporokysts, sporoducts, and release of sporozoites. 1 SEM micrograph of a *Gregarina blaberae* sporokyst with numerous sporoducts. 2 Dehiscence of a *Stylocephalus longicollis* sporokyst is accomplished by a simple fracture of the wall and the chains of spores are observed by SEM between the cyst wall (on the right) and the residual pseudocyst (on the left). 3 DIC

micrograph of *Selenidium mesnili* spores, containing four sporozoites (S). 4 Long chains of *G. blaberae* sporocysts after the sporokyst dehiscence. 5 TEM section through two adjacent sporocysts of *Stylocephalus africanus*, connected by a "ligament-like" structure (From 1, 4 to Desportes and Schrével 2013; 2 to Desportes 1975; to 3 Schrével 1971; 5 to Desportes 1970)

Eugregarines spores are ovoid with eight sporozoites.

The sporulation is the mechanism involved in the releasing of matures spores from the cyst. Several types of sporulation are known.

In eugregarines such as the Lecudinae, Actinocephalidae, and Stylocephalidae, the spores are disseminated by simple rupture of the cyst wall. In families of the Gregarinidae, Labbé, 1899 and Monoductidae Ray and Chakravarty, 1973, the spores are disseminated through long tubes called sporoducts (“spore tubes”) (Fig. 29 (1)). In *G. blaberae*, 7–18 sporoducts are formed at the sporokyst surface but only a few are involved in sporocyst dissemination. In the families Didymophyidae and Monoductidae, respectively, found in beetles and myriapods there is only one sporoduct. In the Dactylophoridae, also parasitic in myriapods, the rupture of the cyst involves a swelling of the pseudocyst. Interestingly, the pseudocyst consists of the residual contents of the male gamont. This is due to the fact that the part of the male gamont required for the formation of the microgametes is quite reduced comparatively to the female gamont which does not contribute to the formation of the pseudocyst due to its transformation into macrogametes. The exposure of the cyst to humidity induces the dilatation of the pseudocyst and the subsequent rupture of the wall.

The released spores from *Stylocephalus* and *Gregarina* can form long monete chains (Fig. 29 (2, 4)) with “ligament like structures” (Fig. 29 (5)) that stabilize the chains.

The dissemination of the spores within the host is also reported. It occurs in gregarines living in the coelomic cavities of earthworms, also in intracellular neogregarines. In such cases, the possible ways of transmission can be necrophagy or cannibalism.

Biogenesis of the Sporozoites

In Eugregarines, after the three metagamic mitoses, eight sporozoites are differentiated in the peripheral cytoplasm of the sporoblast according to a budding process. The MTOC plays a major

role in the establishment of sporozoite polarity. Membranes surrounding the MTOC expand progressively, isolating the cytoplasm of the future sporozoite from that of the rest of the sporoblast. The IMC is formed from endoplasmic reticulum vesicles and Golgi vesicles during early budding (Fig. 30 (1)). This expansion of the plasma membrane and IMC is accompanied by a concomitant development of the subpellicular microtubules from the MTOC. Between the MTOC and the nucleus of each forming sporozoite, characteristic anterior organelles of Apicomplexa will be formed: rhoptries, micronemes, and dense granules (Fig. 30 (3)). The first characteristic apical organelle to be identified in the budding of the *Diplauxis hatti* sporozoite is the large clear vesicle of the rhoptry (Fig. 30 (2)). There is only one rhoptry in the Eugregarine *D. hatti* sporozoite (Fig. 30 (1–2)) (Prensier et al. 2008). Numerous micronemes appear at the end of the sporozoite differentiation (Fig. 30 (3)). They have the appearance of long-neck bottles. In the *Selenidium* Archigregarines, the rhoptries and micronemes are very numerous and the trophozoites can be considered as “Hypersporozoites.” The large disparity between the number of rhoptries and micronemes in Eugregarines and those in other Apicomplexa could be linked to the extracellular development of their trophozoites where they are used to modify the host’s cells in order to produce nutrients able to be absorbed through the mucrons and epimerites. In other Apicomplexa such as *Toxoplasma* and *Plasmodium* which have intracellular stages, the rhoptries are used in the production of parasitophorous vacuole.

The sporoblast cytoplasm not incorporated into sporozoites forms the “residual body” of the spore with numerous amylopectin granules and lipid droplets (Fig. 29 (3)). In contrast, during the evolution of Apicomplexa, such as Hematosporidia (*Plasmodium*, *Babesia*, *Theileria*) parasites mainly of homeothermic vertebrates, the sporozoites are not inside a spore and their life cycles occur in blood or hepatic cells so the disappearance of amylopectin granules could be an example of

Gregarines, Fig. 30 Biogenesis of the *Diplauxis hatti* sporozoite (1–3) and transformation of the *Stylocephalus* sporozoite into trophozoite (4). 1 Budding of a sporozoite with the appearance of micronemes (mn) and of a rhoptry. 2 Anterior region of a sporozoite showing the invagination process of the cortical complex, the Golgi apparatus (G) in the front of the nucleus and the first rhoptry vesicle (R).

3 Transverse section of a mature spore with eight sporozoites around a cytoplasmic residuum; Am, amylopectin granule; mn, microneme; N, nucleus; R, rhoptry, sw sporocyst wall. 4 Drawings of growth stages of the *Stylocephalus* epimerite inside the host cell and enlargement of the epimerite in contact with the protomerite (From 1–3 to Prensier et al. 2008; 4 to Desportes 1970)

a regressive physiology, as proposed by André Lwoff (1944).

The transition between the sporozoite and the tricystid trophozoites is assumed after the

fixation to the host cell and the progressive enlargement of the epimerite in the front of the conoid at the apex of the zoite (Fig. 30 (4)).

Host-Parasite Interactions

Behavior of Gregarines and Host Specificity

Archigregarines are intestinal parasites and Eugregarines are intestinal or coelomic parasites. Some coelomic gregarines have special host targets such as testes (*Gonospora testiculi* in the gastropod *Cerithium vulgatum*), oocytes (*Gonospora minchini* in the polychaete *Arenicoles* (*Arenicola*) *ecaudata*), nephridia (*G. arenicolae* in *A. ecaudata*), and hemal system (*Lithocystis* species in the echinoid *Echinocardium cordatum*). Neogregarines invade fat bodies, haemocoel, malpighian ducts, and intestines of Diptera.

Host specificity is a rather complex problem due to the low number of experimental data. Some marine coelomic gregarines exhibit a strict host specificity as *Diplauxis hatti* present in *Perinereis cultrifera* but not in *Neanthes* (*Nereis*) *diversicolor* two polychaetes belonging to the Nereidae family common in the British Channel., or *Gonospora minchini* and *G. arenicolae* in *Arenicolides* (*Arenicola*) *ecaudata* but not in the most common *A. marina*. In intestinal gregarines, such as *Lankesteria* gregarines, the host specificity is strict in their own Tunicata (Ormières 1965), but cross infections of *Gregarina ovata* are successful in *Forficula auricularia* and in *F. decipiens* (Ormières 1975).

Interestingly gregarines are the host of specific microsporidia from the Metchinokellevidae family. These microsporidia are parasite of marine intestinal gregarines from the Lecudinidae family and Selenidiidae.

Synchronization Between the Coelomic *Diplauxis hatti* Gregarine and Its Polychaete *Perinereis cultrifera* Host and Other Examples in Insects

The life-cycle of the coelomic *Diplauxis hatti* gregarine is a unique example of adaptation to its host *Perinereis cultrifera* polychaete. The sexual phase of the gregarine occurs at the same time as the sexual maturation of the host (Fig. 31 (1)). This polychaete is characterized by a metamorphosis called epitoky where the sexual maturation is accompanied by somatic modifications of the posterior metameres of the worm. This epitoky

status occurs in the last six months of the three-year life cycle of the *P. cultrifera* (British Channel and Atlantic Ocean). The release of the worm gametes is concomitant with the *D. hatti* spores. In the 15 min post fertilization a jelly coat is secreted around the polychaete eggs where numerous *D. hatti* spores are stuck. As the development of this polychaete is direct, the egg eclosion (hatching) release young larva (notochete) with few segments 5–8 days post fertilization. The young larva ingested part of the jelly coat covered with spores and the sporozoites are released in the intestinal lumen as shown experimentally.

During the transepithelium migration (96 h), the sporozoites transform into trophozoites and near the basal lamina these trophozoites are paired and migrated in the host coelom. These small paired associations (10–20 µm) in the first week of the polychaete life cycle undergo slow growth (50–60 µm) after the first year and exhibit pendular motility.

In contrast when the polychaete enters into gametogenesis and moves from the atokous to epitokous status, a spectacular growth of the *D. hatti* is observed, and it produced large paired cells (500–600 µm) with strong metabolic motility. At this stage the paired cells are syzygy and start the gamogony with the secretion of the cyst wall and the production of about 1,000 of male gametes and the same number for female gametes. After fertilization, the *D. hatti* zygotes differentiated eight sporozoites in each of the thousand spores. During the nuptial dance of the worms (May–June at Roscoff, France) the host gametes and the parasite spores are ready for their dissemination. Experimental data demonstrated that the induction of the *D. hatti* sexual stages are under the control of cerebral complex of the *P. cultrifera* (Fig. 31 (2)) (Durchon and Vivier 1964). This situation illustrates that the epitoky induces activation of the molecular programs that control the gamogony as well as the sporogony with the infectious sporozoite stages.

The synchronization of the gregarine life cycles with the host development also occurs in gregarines infecting insects such as mayflies, mosquitoes, or butterflies. Generally, the

Gregarines, Fig. 31 Tissue and coelomic stages during the life cycles of the gregarine *Diplauxis hatti* and its polychaete host *Perinereis cultrifera*. **1** The polychaete stages are indicated 0–8 days for the notochete larvae, 1 year for the immature (atokous) stage and 3 years for the mature (epitokous) stage. The parasite intestinal stages (0–3 days) concern the sporozoite, the transformation in trophozoite and syzygy, the long growth vegetative phase (2 years), the sexual phase starts around 2.5 years with the gametes, zygote, spore formation in

the last 6 months of the life-cycle of *P. cultrifera* during the epitoky phase in order to release the host gametes and the gregarine spores at the same time. **2 A** Immature atokous form of *P. cultrifera* worm and its coelomic parasite, *D. hatti*, blocked at the vegetative phase (syzygy form). **B** After decerebration of *P. cultrifera*, the epitokous transformation occurs in the posterior part of the worm with concomitant sexual development of *D. hatti* (From **1** to Prensier et al. 2008, **2** to Durchon and Vivier 1964)

vegetative phase of the life cycle occurs in the larval stages and the sexual phase is completed in adult insects. The encystment of the Enterocystidae, parasites of larval stages of mayflies, is triggered by the transformation of the host into a short-living imago. The gamonts of these gregarines develop in pairs so that they can encyst at any time of their growth as shown by the different sizes of the cysts present in the gut of a same host. In mosquitoes, the trophic stages are also found in larvae and the sexual phase is induced by metamorphosis. The influence of the molting hormones of the host, a Sciaridae, on the syzygy and gamogony was demonstrated in *Neoschneideria schneiderae*.

Pathogenicity

The pathologic effects of gregarine infections are reported in colonies and cultures. In both cases, the density of host population facilitates the transmission of the parasites and increase of parasite load. The neogregarines are a frequent cause of morbidity and mortality, because of the destruction of hosts issues invaded by schizonts. The Lipotrophidae are a cause of mortality in colonies or cultures of insects (Hymenoptera, Lepidoptera) due to the destruction of the host's fat body. Eugregarines such as the *Leidyana apis* can also cause heavy losses in apiculture (Stejskal 1955).

Influence of Environment on the Prevalence of Gregarine Infection

Recent studies have shown that the level of eugregarine infection in insects was influenced by the extent of the plant cover. In the beetles family Carabidae, the highest eugregarine prevalence was reported from uniform woods whereas it is low in fragmented forests and in cultivated fields. Likewise, the prevalence of eugregarines in forestal dragonflies is lower in fragmented biotopes than in uniform woods. The reduction of the plant cover due to anthropopressure results in higher isolation of infected hosts and lower humidity. Apparently the impact of humidity on gregarine infection is less important than host's isolation (Sienkewicz and Lipa 2009).

Taxonomy

The coevolution of the gregarines and their nonvertebrate hosts is demonstrated by the diversity of infecting species and their number, probably close to several hundred thousand species and even more as most known gregarines are reported from the Coleoptera, the class of insects representing one fourth of all known species (Hunt et al. 2007). The utilization of molecular methods allows the detection of gregarines in new hosts. Morphological data should ascertain the occurrence of a true gregarine infection as the amplified sequences could be those of disseminated spores carried by these hosts.

Gregarine species displaying common developmental and morphological features are assembled within a same family. The 43 families presently established are distributed in three orders: Archigregarinorida Grassé 1953 (archigregarines), Eugregarinorida Léger 1900 (eugregarines), and Neogregarinorida Grassé 1953 (neogregarines). Further, the order Eugregarinorida is divided into the suborders Aseptatorina Charkravarty, 1960 and Septatorina Lankester, 1885. The occurrence of a septum in the trophozoites distinguishes Septatorina from the Aseptatorina.

In this classification, the archigregarines and more precisely those placed in the family Selenidiidae are most interesting as concerns the origin and the evolution of the phylum Apicomplexa. Indeed the trophozoite of *Selenidium* is similar to the zoite, i.e., the basic stage involved in the ability of these unicellulars to invade hosts, and in this occurrence marine worms were probably those first infected (Fig. 5).

Among the Aseptatorina, the Lecudinidae and the Monocystidae are the families represented by the higher number of species. The Lecudinidae are widespread in marine worms (mainly polychaetes), sea cucumbers (Holothuria), and freshwater flat worms (Turbellaria). The Monocystidae are restricted to earthworms (oligochaetes). Lecudinidae live in host intestines whereas Monocystidae are coelomic (Fig. 32 (A, B)).

Twenty six families are assigned to the suborder Septatorina. Five families are reported from

Gregarines,

Fig. 32 Gallery of aseptate gregarines. (A, B) Monocystidae: (A) *Nematocystis claviformis* Loubatières 1955, (B) *Monocystis pilosa*, Loubatières 1955. (C) Lankesteridae: *Lankesteria ascidia* Lankester 1872. (D) Enterocystidae: associated gamonts of *Enterocystis fungoides* Codreanu 1940. (E) Diplocystidae: associated gamonts of *Diplocystis zootermopsidis*, Desportes 1963

crustaceans and most known species belong to the Cephaloidophoridae. They are found in the digestive tract of barnacles, copepods, amphipods, krill, and decapods: crabs, hermit crabs, shrimps, and prawns.

The families most represented in Hexapoda are the Gregarinidae and the Actinocephalidae. Gregarinidae are intestinal parasites of silverfish (Collembola) and most insects: cockroaches, termites, crickets, grasshoppers, earwigs, webspinners, true bugs, beetles, snakeflies, sweet bees, daddy-long-legs, and caddiesflies.

The Actinocephalidae develop in the digestive tract of Arachnids, Myriapods, and Hexapods. Three subfamilies are recognized according to the different aspect of their spores: the Acanthosporinae, Actinocephalinae, and Menosporinae. The spores are ornamented with spines in Acanthosporinae, smooth, and biconical

in Actinocephalinae, smooth and crescent-shaped in Menosporinae (Fig. 33 (F', G', H')). These subfamilies are represented by a diversity of genera and species. Interestingly, the Acanthosporinae are rather found in carnivorous, predatory hosts such as the centipedes in myriapods. In hexapods, they infect aquatic larvae and imagoes of damselflies, dragonflies (Odonata), green stoneflies (Trichoptera), caddisflies (Plecoptera), water scavengers beetles (Hydrophilidae), and other coleopterans such as diving beetles (Dytiscidae), rove beetles, ground beetles as well as necrophagous burying beetles. Different species of Acrididae, a predominant family of grasshoppers, are infected with the same species of Acanthosporinae, *Coronoepimeritus amphoriformis* (Fig. 33 (I)).

Other gregarine families are restricted to one host order or family. For instance,

Gregarines, Fig. 33 Gallery of septate gregarines. (A) Actinocephalidae: *Sciadophora phalangii*, Léger 1897 (From Desportes and Schrével 2013); (B) Dactylophoridae: *Grebnickiella gracilis* Schneider, 1887 (length of the trophozoite: about 4 mm); (C) Stenophoridae: *Stenophora dahomeensis* Gasc, Ormières and Bouix, 1975; (D) Gregarinidae: *Amoebogregarina crenata* Bathia and Setna 1924; (E) Cephaloidophoridae: *Cephaloidophora florencae*, Vivarès, 1978; (F–I)

Actinocephalidae. (F–F') trophozoite and spore of *Pileocephalus sinensis* Schneider 1875 (Actinocephalinae); (G–G') trophozoite and spiny spore of *Rhizoniella tenuis* Baudouin, 1971 (Acanthosporinae); (H–H') trophozoite and spore of *Hoplorhynchus gracilis* Hoshide, 1977 (Menosporinae); (I) *Coronoepimeritus amphoriformis* Bosh, 1928; (J) Stylocephalidae: *Stylocephalus micranterei* Théodoridès, Desportes and Jolivet 1964

Dactylophoridae and Stenophoridae are found in Myriapods. Likewise, the Enterocystidae develop exclusively in the larval stages of mayflies (Ephemeroptera). Interestingly, phylogenetic analyses confirm that the Stylocephalidae apparently restricted to the coleopteran family Tenebrionidae (darkling beetles) are also represented by three species in basal insects (bristletails, silverfish) (Clopton 2009). Curiously, no gregarine infection could be detected in stick insects which belong to Orthoptera (Phasmidae).

Neogregarines are distributed in six families. Most known species belong to the Lipotrophidae. They are located in the fat body and coelom of a diversity of insects such as true bugs, bees, ants, scorpionflies, and squirrel fleas. Most infected insects are beetles and true flies. Indeed species of four genera are found in these hosts, whereas only one, the genus *Lipotropha*, is recorded in the other insects. Arachnids (acarids) and Myriapods are also the hosts of Lipotrophidae.

Grellia (syn. Eucoccidium) dinophili

Protococcidian within the body cavity of the Archiannelid *Dinophilus gyrocolliatus*. There is no ► [schizogony](#), only trophonts grow up to gamonts that form male and female gametes. After ► [syn-gamy](#), the ► [oocyst](#) gives rise to sporoblasts (sporocysts) containing the sporozoites.

Griphobilharzia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of schistosomatid worms occurring in Australian crocodiles.

Grocer's Itch

Allergic reaction due to contact with dust or harvest ► [mites](#).

Growth Factors

General Information

Epidermal growth factor (EGF) and insulin-like growth factor I (IGF-I) stimulate cell proliferation; IGF-I is also involved in metabolic functions. Their corresponding receptors are tyrosine kinases phosphorylating intracellular proteins.

Certainly all parasites living in vertebrate hosts come into contact with growth hormone, growth factors, and cytokines from the host, either circulating in the blood or being locally expressed like e.g., insulin-like growth factor I (IGF-I) in the skin. Cytokines of the host are primarily involved in immune responses whereas growth hormone and growth factors are signalling substances regulating, e.g., differentiation and proliferation in parasites.

Pathology

Infection with parasites usually changes titres and cytokine profiles in the host, independently of whether ► [Protozoa](#) or helminths are involved. Interestingly, the infective-stage larva of ► [Brugia malayi](#) produces a cytokine which resembles the host macrophage migration inhibitory factor (MIF) and which is able to modulate the host immune response and to promote parasite survival. Another example of a substance produced by the parasite and mimicking a host hormone is the ► [plerocercoid](#) growth hormone-like factor from spirometrid ► [tapeworms](#). This factor circulates in the blood, binds to the host growth hormone receptor and mimics many of the biological actions of growth hormone.

IGF-I of the host is recognized by *Leishmania mexicana* ► [vacuoles](#) and ► [amastigotes](#) and this external host signal is converted into a parasite signal. First, IGF-I binds to both promastigotes and amastigotes, it stimulates growth in both cell types and leads to a rapid tyrosine phosphorylation of parasite proteins. The pattern of phosphorylated proteins is dependent on the developmental stage. In another protozoan

parasite, *Trypanosoma brucei*, EGF of the host is able to stimulate growth and to activate the signal transduction cascade in the parasite, leading finally to GTP-hydrolysis via small G-proteins. EGF is active at physiological concentrations. In the same species, bombesin, a peptide hormone from the brain and the gastrointestinal tract, also hydrolyses GTP.

Growth Retardation

The presence of specimens of several species of worms hinders the normal growing of their human or animal hosts: *Ascaris*, *Strongyloides*, *Ancylostoma*, *Necator*, etc.

Guide RNA

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Guide RNAs (gRNAs) are small RNA molecules that are encoded in the mitochondrial DNA of kinetoplastid flagellates. These 50–60 nucleotide short gRNAs have a template-like function during the ► [RNA editing](#) process and specify the site

and number of uridylyte residue (U) additions to and occasional deletions from precursor mRNA. gRNA sequences have been identified in several different kinetoplasts, whose total number varies greatly between species and even between different strains of the same species. The minicircle kDNA contains the majority of the gRNA genes that are localized at specific sites within the variable region and are produced from large precursors by nucleolytic processing and 3' uridylation. In *Trypanosoma brucei*, each minicircle can encode 3–5 gRNAs, whereas *Leishmania tarantolae* contains only a single gRNA per minicircle, reflecting less extensive editing as compared to the former species. The maxicircle kDNA also contains a small number of gRNA genes in addition to protein-coding genes, rRNA genes, and cryptogenes. *T. brucei* possesses the greatest kDNA complexity with over 200 minicircle classes that can encode more than 1200 different gRNAs.

Gula

Morphological structure of the Heteroptera (bugs). The head capsule is closed ventrally by a bridge behind the rostrum, so that the rostrum arises not at the hind margin of the head but some distance in front of it. Often the rostrum is brought further forward by a considerable elongation of the head.

Gyalocephalus capitis

Small strongylid nematodes of equids (male 7–10 mm, female 8–13 mm).

Gymnophallidae

Trematode family, the members of which mostly occur in birds. Only one genus

(*Gymnophalloides*) includes a very small parasite of humans, which may occur in large numbers in the intestine or in the biliary system. This worm is characterized by the peculiarities, that the ventral sucker occurs in the posterior quarter of the body and that many tegumental hooks are formed. Intermediate hosts are marine oyster and clam.

Gymnophalloides

Species

G. tokiensis, *G. seoi*.

Morphology

0.5 × 0.3 mm sized trematodes, which are found in the small intestine of birds (oyster catchers) and humans in Korea/Asia. The adults possess a large oral and a small ventral sucker. In addition, there occurs an unique ventral pit, which is situated (as the ventral sucker) in the posterior third of the spiny tegument (with many scales). The first intermediate host is unknown, but oysters are the second one containing the infectious metacercariae. In Korean villages infection rates of up to 46 % were found when diagnosing the thin eggs 25 µm × 15 µm in the faeces.

Symptoms of Disease

Gastrointestinal troubles, fatigue, weight loss, diarrhoea.

Therapy

► [Trematocidal Drugs](#).

Gymnophalloides seoi

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

The name of this digenean trematode is based on Greek: *gymnos* = naked; *phallos* = penis; Seo = Korean helminthologist.

Geographic Distribution/Epidemiology

Korean peninsula, probably also in surrounding countries along the Yellow Sea coast.

Morphology/Life Cycle

This human trematode species, which was already described from mummies in the seventeenth-century, has probably a similar life cycle to ► *Clonorchis sinensis* involving snails as first and fish as second intermediate hosts. This species was rediscovered in living humans in the year 1993 by Lee et al., who showed that the eggs excreted by humans are small sized ($19.8 \pm 2.5 \times 12.1 \pm 0.8 \mu\text{m}$), of elliptical shape, transparent, and thin shelled. For life cycle and treatment see ► *Opisthorchis species*.

H

Habitat

Name

Latin: *habitare* = dwelling.

This term – often used as a synonym of biotope – is the place/region, where a species lives, e.g., where ecological factors allow survival.

► [trematodes](#), cercariae of trematodes (► [Digenea](#)), ► [nematodes](#), ticks.

Habitat Selection

Name

Latin: *habitatio* = dwelling.

Habitat comprises all ecologic factors of the surroundings of an animal (often used as synonym to biotope).

Parasites which actively find and invade their hosts accumulate in favourable habitats, responding to very different environmental stimuli. Short-living stages such as trematode miracidia and ► [cercariae](#) prefer mainly habitats frequented by their potential hosts, whereas many long-living stages such as some nematode infective larvae and ► [ticks](#) primarily select habitats which support their survival. Such stages shift to habitats where an encounter with their hosts is increased when the conditions for their survival are favourable. For mechanisms of habitat selection see ► [host finding](#), miracidia of

Habronema

From Greek: *habros* = fine, *nema* = filament. Genus of ► [Nematodes](#), ► [Stomach worms](#).

Habronema species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *habros* = smooth, tiny; *mega* = large; *nema* = filament. Latin: *musca* = fly; *maius* = larger; *stomum* = mouth. English: stomach worms.

Geographic Distribution/Epidemiology

Worldwide; in Europe high prevalence rates during summer (often up to 50 %).

Habronema species, Fig. 1 Anterior pole of *H. muscae*. Note the lateral wings (Prof. Dr. Schuster, Dubai)

Morphology/Life Cycle

The adults of the species *Habronema muscae* and *H. majus* (syn. *H. microstoma*) are nematodes, which live in the intestine of horses.

H. muscae (Fig. 1): The adults appear yellowish orange. ♂ = 8–14 mm long; ♀ = 12–22 mm long. Their mouth capsule is toothless. Males possess caudal wings, a 2.5 mm long and a 0.5 mm long spiculum, while the vulva of the female is situated in the anterior third of the body. The eggs measure $40\text{--}50 \times 10\text{--}12\text{ }\mu\text{m}$ and contain the larva 1.

H. majus (Fig. 2): The whitish adults possess two teeth in their mouth capsule. Males measure 9–16 mm, have no caudal wings, and the two spicula measure 350 and 750 μm in length. The females measure 15–25 mm in length and have a short vagina and ovoid ovoprojector. Their eggs reach sizes of $45\text{--}50 \times 16\text{ }\mu\text{m}$ and contain the larva 1 when excreted.

The adults live in the mucous layer of the stomach in the region of the fundus. The females excrete thin-walled eggs, from which the larva 1 hatches often already inside the intestine. Their life span inside the feces is short, and for further development it is needed that fly larvae ingest them. *Musca domestica* larvae are intermediate hosts for *H. muscae*, and larvae of *Stomoxys calcitrans* act as vectors for *H. majus* in Europe (some other fly species may also be involved mechanically in the transmission).

Habronema species, Fig. 2 Anterior pole of *H. majus*. Note the absence of lateral wings (Prof. Dr. Schuster, Dubai)

From the intestine of the fly larvae the larva 1 enters the body cavity, where they grow via two molts until larva 3. This process is finished when the larvae of the flies start pupa formation. Within the adult flies the larvae 3 migrate into the head. As soon as a fly sits on the lips or skin of a host the larvae 3 leave the mouthparts and are engorged by the horse, when licking at the skin. Having reached the intestine the worms reach maturity within 2 months inside the stomach. If larvae 3 get in contact with little wounds at the skin (at lips, eyelids, feet, etc.) they enter the skin layers and induce poorly healing wounds (so-called summer sores), which leave often large scars especially in the case of bacterial superinfections (Fig. 3).

Symptoms of Disease

Low-graded infections introduce mostly only slight symptoms of disease which remain often undiagnosed. Severe infections may induce nodules in the stomach wall, and in cases of entering the peritoneal cavity considerable peritonitis

Habronema species, Fig. 3 Horse with a typical summer sore at the right foreleg (Prof. Dr. Schuster, Dubai)

symptoms may follow. The summer sores due to the larvae that had entered the skin introduce itching, open wounds, granulomas, and generalized dermatitis.

Diagnosis

The thin-walled eggs respectively the free larvae 1 may be isolated from the feces of the horses by help of concentration methods (e.g., ► [flotation](#); ► [S.A.F.C.](#) or ► [Baerman technique](#)).

Infection

Oral uptake of larvae 3 that had been left in the mouthparts of infected flies (= intestinal habronematosi) or by entering of larvae 3 into skin wounds (= skin habronematosi).

Prophylaxis

Repeated removal of horse feces, protection of horses from flies.

Incubation period

One to four weeks.

Prepatent period

About 2 months.

Patency

Four to fifteen months.

Treatment

Treatment of stomach habronematosi: ivermectin (0.2 mg/kg body weight, orally) or moxidectin (0.4 mg/kg body weight, orally). Ivermectin also works in skin habronematosi (sore) as well as local application of a 10 % metrifonate solution.

Habronemiasis, Habronemosis

The larvae of ► *Habronema* spp. and *Draschia* (► *Filariidae*) cannot penetrate normal skin. However, cutaneous invasion and lesions occur when larvae are deposited near open wounds by their vectors. Areas frequently involved include the withers, the lower limbs, the medial canthus of the eye, and the urethral process and prepuce of the male. The gross lesions rapidly become progressive and proliferative in nature, comprising ulcerated tumorous masses of red-brown granulation tissue. The sore is already painful before the development of granuloma. This causes an intense ► [pruritus](#), and infected animals exacerbate the condition by biting and rubbing the lesion.

Therapy

► [Nematocidal Drugs, Animals.](#)

Hadjelia truncata

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This species belongs to the spirurid nematodes of the family Habronematidae parasitizing in the gizzard of several avian species (also in magpies, cuckoos, and pigeons, *Columba livia*). Males reach a length of 6.5–9 mm, while females are longer (12–16.5 mm). Intermediate hosts are beetles.

Haemabartonella

Genus of rickettsiales, transmitted by blood suckers.

Haemagogus

Genus of mosquitoes, which may transmit the virus of Yellow fever.

***Haemaphysalis* Species**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *haima* = blood; *phyra* = bladder. Latin: *punctum* = injection point; *concinna* = tiny; *inermis* = without weapons. English: red ticks.

The genus *Haemaphysalis* comprises about 165 described species, which occur worldwide. Especially numerous species are found in Asia and in Africa. In Europe three species are endemic, but their biotopes stretch out in many Eastern and Mideastern countries (Figs. 1, 2).

Haemaphysalis punctata

The females of this eyeless species reach unfed only in a length of up to 3.5 mm, but measure engorged up to 12 mm. Males range between 2.8 mm and 3.0 mm. They appear unfed grayish reddish with pigments in their body cover. These ticks need obligatorily three hosts within their life cycle so that the duration for one single generation may last 1–3 years. They occur in different habitats reaching from humid regions with numerous plants until semiarid regions in Central Asia and North Africa. However, they occur mainly in small biotopes, which are scattered island-like over Europe and Asia. Their hosts and potentially transmitted agents of diseases are listed in Table 1. Diagnosis in cattle can be done by inspection of the udder, which is a preferred biting site.

Haemaphysalis concinna

The females of this eyeless species (English: relict tick) measure unfed about 3.5 mm in length

Haemaphysalis Species, Fig. 1 Diagrammatic representation of the shape of the scutum and eye position of different tick genera. Note that *Haemaphysalis* ticks are eyeless like the stages of *Ixodes* species

(engorged ~1.3 cm), while males have lengths of about 2.8–3 mm. They are like humid biotopes within forests and are often found there together with *Ixodes ricinus*. They occur in Europe stretching from France, via Germany, Hungary, and eastward until China and Japan. Their preferred hosts and potentially transmitted agents of diseases are listed in Table 1.

Haemaphysalis inermis

The eyeless females of this rarely occurring so-called winter tick measure 2–3 mm in an

unfed status and reach engorged only 8 mm in length. Males measure around 2.5 mm in length. They all prefer biotopes, where cervids occur in different types of forests. As adults they are found on cervids during winter time (November until April), which led to its trivial name, winter ticks. Their larvae and nymphs are only rarely found on animals, since they suck for a rather short period and fall quickly down to soil, where the molting period needs often up to 1 year. However, these ticks may also attack humans. Their distribution region is stretched from France via countries of the Balcony until Iran and South Asia. Their hosts are listed in Table 1.

Haemaphysalis Species,

Haematobia

Genus of the fly family Muscidae, synonym to *Liperosia* (*L. irritans*) and *Siphona irritans*. *H. irritans* (small meadow biting fly, 3–5 mm long) occurs worldwide, sucks blood up to 20 times per day, and develops four to five generations per year. *H. stimulans* (synonym: *Stomoxys*

stimulans and *Haematobosca stimulans*) is the so-called large meadow bite fly with a length of up to 7 mm. Its activity is mainly in late summer and autumn. While *H. irritans* practically lives on the host, *H. stimulans* leaves the host for the night. Ectoparasiticides.

Haematobia irritans

Small biting fly (3–5 mm), which occurs worldwide and appears grey, green-brown, or black with brown legs. It feeds up to 20 times per day at cattle sitting head down. The larvae develop in faeces of cattle – in Europe up to five generations occur (► [Tabanids](#), Fig. 1). Related species are *Haematobia (Stomoxys) stimulans* = large biting fly (5–7 mm), *Hydrotaea irritans* (head and udder fly (5.5–7 mm), and ► [Stomoxys calcitrans](#).

Therapy

Ectoparasitocidal drugs.

Haematopota

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *haima* = blood; *potamos* = river.

Haematopota, Fig. 1 Macrophoto of a female *H. pluvialis* on the editor's hand

The genus name refers to the fact that after bites of these bloodsuckers, always a droplet of blood can be seen on the biting site.

General Information

The females of this genus of dipteran blood-suckers (family Tabanidae) suck blood by help of their sawing mouth parts. They occur in Europe and general in Nearctic, Palaearctic, and oriental regions. In Europe the species *Haematopota pluvialis* is found in large numbers, while the cleg *H. maculosifacies* occurs in the Americas. These species are diurnally active and follow their moving prey (also humans) by the help of their large compound eyes. They breed in mud or damp soil and grow up passing up to 13 larval stages before pupation (Fig. 1).

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Brachyceran species of the family Tabanidae, the specimens of which reach a body length of 6–11 mm and occur in Europe, Asia, and North Africa often in large numbers along creeks. The attacking specimens approach silently – often prior to rainfall – to their hosts, where they suck blood. Thus they obtained the trivial name “rainfall tabanids.” Their bite is rather painful as that of *Tetraglenes crassicornis*, which occurs in Europe and Asia.

Haemobartonella canis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Rickettsial agent of disease, which occurs as small 0.2–0.5 µm sized spheres singly or in chains on the surface of red blood cells of dogs. Similar stages in cats have been described as *H. felis* (syn. *Eperythrozoon felis*). They are ingested during blood sucking of ► *Haemaphysalis leachi* ticks (or related species). They are reproduced inside the intestine, are excreted with the feces, and thus reach the skin of hosts, where they may enter the body via wounds during scratching. Since erythrocytes may become destroyed, haemobartonellosis is always connected with anemia and apathia of infected dogs. **Treatment** of this disease can be done with doxycycline or imidocarb.

H

Haementeria

Giant leech, which may grow up to 30 cm.

► [Leeches](#).

Haemodipsus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Parasite in the red blood cells of turtles.

Haemonchosis

Haemonchosis is a common and severe disease of the ruminant abomasum in many parts of the

world. ► *Haemonchus contortus* infects mainly sheep and goats, while *Haemonchus placei* occurs mainly in cattle. The pathogenesis of *Haemonchus* infection is the result of ► **anaemia** and hypoproteinaemia caused by the bloodsucking activity of the parasite. Large numbers of *Haemonchus* administered to sheep cause changes resembling those occurring in ► **ostertagiosis**, including rises in abomasal pH and increased plasma pepsinogen. However, the latter two effects do not contribute to the spontaneous disease. The following description is mostly based on studies on ovine haemonchosis. The hyperacute form occurs in animals exposed over a short period of time to thousands of parasites, and is rare. The animal bleeds to death within a week, losing 200–600 ml of blood/day. In many cases there are no preliminary signs and death is sudden. In others there is an extreme anaemia and black faeces. Death occurs before compensatory erythropoiesis can take place, within 7 days. In the acute disease animals of all ages show anaemia, bottle jaw, and dark faeces. There are conflicting reports as to whether ► **anorexia** occurs and it has even been reported that sheep eat more than they normally do. Animals lose weight, are weak and lethargic, and lose wool. Ewes suffer agalactia, so that their lambs may become emaciated and die from malnutrition. The anaemia of acute haemonchosis develops in three phases. The first phase which occurs during the pre-patent period is characterized by a fairly dramatic fall in packed cell volume, although serum iron at this stage is normal. This is considered to be the result of blood loss caused by immature worms, at a time when the haemopoietic system of the host is not fully mobilised to compensate it. In the second stage (from about 1–2 months) the packed cell volume does not decrease any further, because of the mobilisation of the haemopoietic system and the high serum iron concentrations. However, since the capacity of the sheep infected with

H. contortus to reabsorb haemoglobin iron is limited, the iron reserves rapidly become depleted, which progressively leads to the third stage of the anaemia i.e., a low serum iron accompanied by a marked drop in packed cell volume. This indicates a dyshaemopoiesis due to iron deficiency and possibly to reduction in the availability of amino acids. ► [Hypoalbuminaemia](#) occurs. Chronic haemonchosis may last for 2–6 months. Only a few adult worms (100–1,000) can cause a seepage of blood into the abomasum accounting at most for 50 ml/day. Anaemia is not present as compensatory erythropoiesis takes place, which depletes serum iron. The animal looks malnourished, with progressive loss of weight and wool-peeling in adult animals, and stunting of growth in lambs. The condition is aggravated by poor quality grazing as occurs in Africa and other tropical regions. A marked anaemia develops in terminal cases when iron and protein for erythropoiesis are depleted.

Haemopsis sanguisuga

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *haima* = blood; *ophis* = snake; Latin: *sanguis* = blood; *sugere* = sucking.

This leech, which is found in the whole of Europe and North Africa, belongs to the order Gnathostomidae of the Hirudinea and is also called “horse leech.” Both the scientific and trivial names are wrong, since this leech, which reaches at the adult stage a length of up to 15 cm, lives in freshwater biotopes and neither sucks blood nor attacks horses, but it engorges other annelid worms and insect larvae – thus living as a predator. Its upper side appears brownish, while its flattened basal side looks yellowish green. When

named it was mixed with another leech, who got also the trivial name “horse leech,” but is now correctly named as ► *Limnatis nilotica*. This 8–12 cm leech indeed is able to enter into the mouth, esophagus, or nasal cavities of many animals, including dogs, cattle, horses, and camels during their water uptake from little water ponds in regions around the Mediterranean Sea.

Haemoproteus Species

Gediminas Valkiūnas
P. B. Šivickis Laboratory of Parasitology,
Nature Research Centre, Vilnius, Lithuania

Synonyms

Haemamoeba (partim); *Haemocystidium* (partim); *Halteridium*; *Laverania* (partim)

Etiology

Haemoproteus parasites are classified as members of the phylum Apicomplexa (syn. Sporozoa), order Haemosporida, family Haemoproteidae.

Important Species

Species of *Haemoproteus* have been traditionally distinguished by morphology of gametocytes and their influence on host cells (Fig. 1) and also by limited experimental information about vertebrate host specificity. Over 160 species have been described and named. Recent studies on diversity of mitochondrial and nuclear genes of avian haemoproteids indicate that the number of existing species may be manyfold higher. Type species is *Haemoproteus columbae* (Fig. 1, 4, 8; Table 1).

Main Diagnostic Characters

Haemosporidian parasites with merogony (schizogony) in cells of fixed tissues of vertebrate

Haemoproteus Species, Fig. 1 Different morphological forms of mature gametocytes of *Haemoproteus* spp. from the blood of the Eurasian Sparrowhawk *Accipiter nisus* (1, 5), the Common Blackbird *Turdus merula* (2, 6), the Tawny Owl *Srix aluco* (3, 7) and the Rock Dove *Columba livia* (4, 8): 1–4 – macrogametocytes, 5–8 – microgametocytes of *Haemoproteus* (*Parahaemoproteus*) *nisi* (1, 5), *Haemoproteus* (*Parahaemoproteus*) *minutus* (2, 6), *Haemoproteus* (*Parahaemoproteus*) *synnii* (3, 7), and *Haemoproteus* (*Haemoproteus*) *columbae* (4, 8). These

species can be readily distinguished based on morphology of their blood stages due to markedly different size and shape of mature gametocytes, different size and shape of pigment granules, different patterns of growth in infected erythrocytes, and presence of volutin granules in some gametocytes. Arrows – nuclei of parasites. Triangle arrowheads – pigment granules. Simple arrowheads – volutin granules. Giemsa-stained thin blood films. Bar = 10 μ m

hosts. Merogony is absent from circulating blood cells. Gametocytes develop in red blood cells and contain malarial pigment (hemozoin) (Fig. 1). Sexual process and sporogony take place in biting midges (Ceratopogonidae) and louse flies (Hippoboscidae). Widespread parasites of birds; several *Haemoproteus* species have been described in reptiles, but their relationships with bird parasites remain insufficiently studied.

Two subgenera, i.e., *Parahaemoproteus* and *Haemoproteus*, are widely accepted in genus *Haemoproteus*. The great majority of bird parasites belong to the subgenus *Parahaemoproteus*, which include ceratopogonid transmitted species with small oocysts (<20 μ m in diameter). Both ends of sporozoites are approximately equally pointed in species of *Parahaemoproteus* (Fig. 2, 8). Species of the subgenus *Haemoproteus* are bird parasites transmitted by louse flies; these

parasites produce large (>20 μ m in diameter) oocysts (Fig. 2, 7). One end of sporozoites is more pointed than the other in species of *Haemoproteus* (Fig. 2, 9). Recent phylogenetic analyses based on mitochondrial gene sequences indicate that species of *Parahaemoproteus* and *Haemoproteus* are closely related sister groups, supporting the traditional subgeneric classification of these parasites.

Life Cycle and Epizootiology

The life cycle of *Haemoproteus* parasites is obligate heteroxenous. The parasites develop in vertebrates (mainly birds) and vectors, which are blood-sucking dipterans belonging to the Ceratopogonidae and Hippoboscidae. Sexual process takes place in the vectors. Complete life

Haemoproteus Species, Table 1 Important *Haemoproteus* species

Subgenus and species	Type avian host	Vector	Distribution	Pathogenicity
<i>Haemoproteus</i>				
<i>H. columbae</i>	<i>Columba livia</i>	<i>Pseudolynchia canariensis</i> <i>Pseudolynchia brunnea</i> <i>Microlynchia pusilla</i>	Mainly countries with warm climates	-/+
<i>H. palumbis</i>	<i>Columba palumbus</i>	<i>Ornithomyia avicularia</i> <i>Pseudolynchia canariensis</i>	Eurasia	Unknown
<i>H. iwa</i>	<i>Fregata minor</i>	Probably <i>Olfersia spinifera</i>	Oceanic islands	Unknown
<i>Parahaemoproteus</i>				
<i>H. handai</i>	<i>Psittacula cyanocephala</i>	<i>Culicoides nubeculosus</i>	Widespread in tropics	-/+
<i>H. lophortyx</i>	<i>Lophortyx californica</i>	<i>Culicoides bottimeri</i>	Nearctic	-/++
<i>H. masoni</i> (syn. <i>H. meleagridis</i>)	<i>Lagopus scoticus</i>	<i>Culicoides edeni</i> and many other <i>Culicoides</i> spp.	Holarctic	-/++
<i>H. minutus</i>	<i>Turdus merula</i>	Unknown	Palearctic	-/++
<i>H. nettionis</i>	<i>Anas castanea</i>	<i>Culicoides downesi</i>	Cosmopolitan	-/+
<i>H. passeris</i>	<i>Passer hispaniolensis</i>	<i>Culicoides</i> spp., needs to be identified	Cosmopolitan	-/+
<i>H. tartakovskyi</i>	<i>Loxia curvirostra</i>	<i>Culicoides impunctatus</i>	Palearctic	Unknown
<i>H. parabelopolskyi</i>	<i>Sylvia atricapilla</i>	<i>Culicoides impunctatus</i>	Palearctic	-/+

Notes: -/+—relatively benign in adapted avian hosts, but is pathogenic in chicks or/and non-adapted hosts; -/++—relatively benign in adapted avian hosts, but is virulent and sometimes even lethal in non-adapted hosts

cycles and details of development remain unknown for the great majority of described species. The exoerythrocytic development has been fragmentarily investigated, but knowledge on this issue is particularly important for better understanding pathology caused by these parasites.

During blood meal, the vectors inoculate sporozoites (Fig. 2, 8, 9) in vertebrate hosts giving rise to exoerythrocytic meronts (schizonts), which undergo asexual division in cells of the fixed tissues of the hosts (Fig. 3, 1–3). The merogony is absent from blood cells. Numerous uninuclear merozoites, which are asexual stages of spreading within the vertebrate host, develop in exoerythrocytic meronts. The latter develop mainly in the endothelial cells and probably in fixed macrophages, while in some species the meronts mature in myofibroblasts. There are several generations of the exoerythrocytic development, during which the parasite gradually adjusts to the host. Most frequently, meronts are found in the lungs (Fig. 3, 1, 3) and less often in the liver, spleen

(Fig. 3, 2), kidneys, heart, skeletal musculature, and other organs. The meronts are markedly variable in shape and size; their length usually does not exceed 100 µm. During development, large exoerythrocytic meronts can split into individual parts (cytomeres, Fig. 3, 2) containing numerous nuclei.

In some species (*Haemoproteus handai*, *Haemoproteus masoni*), huge meronts (megalomeronts) develop in the endothelial cells of capillaries, in myofibroblasts of the skeletal musculature, in the heart muscle, and sometimes in other muscular organs. Megalomeronts are significantly larger than meronts developing in the lungs and other organs (Fig. 3, 4). The length of the largest megalomeronts exceeds 400 µm; they can be observed without microscope on surfaces of the damaged organs. Megalomeronts reach maturity between 2 and 3 weeks post exposure and rupture to release small numerous spherical merozoites. As a result of the exoerythrocytic merogony, there is an avalanche growth of the

Haemoproteus Species, Fig. 2 Vector stages of *Haemoproteus* (*Parahaemoproteus*) *fringillae* (1–6, 8) and *Haemoproteus* (*Haemoproteus*) *palumbis* (7, 9): 1 – macrogamete, 2 – microgamete, 3 – fertilization of macrogamete with microgamete, 4 – zygote, 5 – ookinete, 6, 7 – oocysts, 8, 9 – sporozoites. Note the presence of a “vacuole” in zygote (4); large size of the *H. palumbis* oocyst, which possesses numerous roundish germinative centres (7); sporozoites, which are with approximately equally pointed ends in species of the subgenus

Parahaemoproteus (8), but with one end more pointed than the other in species of the subgenus *Haemoproteus* (9). Short arrows – nuclei of parasites. Triangle arrowheads – pigment granules. Simple arrowhead – a “vacuole”. Long arrows – oocysts. Giemsa-stained thin blood films (1–5, 8, 9), a whole mount of the midgut of *Culicoides impunctatus* (6), and a formalin fixed and haematoxylin-eosin stained histological section of the midgut of hippoboscids fly *Ornithomyia avicularia* (7). initial source of infection. Exoerythrocytic merozoites initiate a new cycle of the merogony and/or invade erythrocytes and develop into gametocytes (Fig. 1).

Prepatent period for the majority of investigated *Haemoproteus* species varies between 10 and 17 days. Gametocytes develop in mature erythrocytes (Fig. 1, 1–8). More than one (sometimes up to 15) merozoites can penetrate

into an individual erythrocyte. Multiple infection of one erythrocyte by several parasites is a function of the intensity of parasitemia. Usually, one or two parasites gain the maturity. Malaria pigment (hemozoin) is the product of digestion of host hemoglobin; it is well visible in gametocytes as discrete granules of golden-brown, brown, or black color (Fig. 1, 2, 5, 7). The number, form, and position of pigment granules in gametocytes

Note the markedly different size and shape of nearly mature exoerythrocytic meronts (1–3) and megalomeronts (4) in different parasite species. Bars = 10 μ m

H

are important characters used in taxonomy on species level. Together with the true malarial pigment (hemozoin), more or less compact gatherings of matter called volutin are often found in the gametocytes of certain species (Fig. 1, 3, 7). The granules of volutin, if stained by Giemsa, usually obtain various hues of the violet color and sometimes have azurophilic tints. They are usually readily distinguishable from pigment granules by their lesser light refraction. In some species, volutin granules are associated with pigment granules, making the latter difficult to visualize (Fig. 1, 4, 8). The nature and role of volutin granules are still not completely understood in *Haemoproteus* spp. Gametocytes capable of gametogenesis appear within 2–6 days after penetrating of merozoites in erythrocytes. Afterward, the capability of gametocytes to produce gametes decreases. A small number of viable gametocytes (often less than 1 per 1000 erythrocytes) is usually maintained in the blood of infected birds due to the weak merogony in internal organs during the period, when transmission occurs in nature.

Gametocytes possess the sexual potency (they produce gametes). Gametocytes, which produce

macrogametes, are known as macrogametocytes (Fig. 1, 1–4), as distinct from microgametocytes (Fig. 1, 5–8), which produce microgametes. Macrogametocytes are usually easily distinguishable from microgametocytes due to their sexual dimorphic characters (compare Fig. 1, 1–4 with Fig. 1, 5–8), which are a more intense staining of the cytoplasm with Giemsa and a compact nucleus with clear margin (there are exceptions). Pigment granules (hemozoin) tend to gather at the ends of elongate gametocytes in microgametocytes (Fig. 1, 5, 8), which is not generally a characteristic of macrogametocytes (there are exceptions). Morphology of gametocytes and the patterns of their impact on infected erythrocytes are important taxonomic characters used for *Haemoproteus* species identification (Fig. 1). Gametocytes are infective for vectors.

The parasites persist in birds. Once infected and having survived the initial infection, a bird usually maintains the parasites for many years or even for the lifelong period, thus being the source of infection for vectors. A relapse of parasitemia occurs in most of *Haemoproteus* species during the reproduction period of vertebrate hosts; that

facilitates infection of vectors and transfer of infection to the offspring. Mechanism of relapse remains insufficiently investigated. Gonadotrophic hormones are likely involved. Experimental evidence suggests that increases in photoperiod and subsequent physiological changes in levels of hormones such as melatonin, which regulate circadian rhythms, are important stimuli for initiating relapses among species of *Haemoproteus* in temperate regions.

Gametocytes undergo gametogenesis (Fig. 3, 1, 2) in the midgut of the vectors, resulting in a sexual process of the oogamy type (Fig. 3, 3). This process is extremely rapid and occurs within several minutes after ingestion of mature gametocytes. Main stimuli for the beginning of the gametogenesis are the fall in temperature and the change of the oxygen and carbon dioxide concentration, when the blood is transferred from the vertebrate host to the vector. Sexual process can be readily induced in vitro conditions when blood containing mature gametocytes is exposed to air. A macrogametocyte produces one rounded macrogamete (Fig. 3, 1), while microgametocytes undergo the exflagellation and form eight motile thread-like microgametes (Fig. 3, 2). Fertilization occurs extracellularly (Fig. 3, 3). Zygote (Fig. 3, 4) is transformed into an elongate motile ookinete (Fig. 3, 5). The latter penetrates through a peritrophic membrane and through the epithelial layer of the midgut. The length of microgametes, morphological features of zygotes, patterns of zygote transformation into ookinete, the sizes of ookinetes, and the rate of ookinete formation under standard conditions markedly differ in many *Haemoproteus* species. The ookinetes round up under the basal lamina and develop into oocyst, which is surrounded by a capsule-like wall built from the material of the host (Fig. 3, 6, 7). During oocyst development (sporogony), numerous uninuclear elongate bodies (sporozoites) develop (Fig. 3, 8, 9). After maturation of oocysts, the sporozoites get into the hemocoel and next penetrate into the salivary glands of the vector. Sporozoites are infective for birds. Transmission occurs when sporozoites are injected by the vector into the vertebrate hosts with salivary gland secretion during its blood meal.

It is worth noting that, contrary to the closely related malaria parasites of the genus *Plasmodium*, the gametogenesis in *Haemoproteus* parasites does not require additional stimuli, e.g., the presence of vector-derived xanthurenic acid and blood-derived factors. As a result, the extensive sexual process and ookinete development of *Haemoproteus* spp. occur in the digestive tract located not only in the midgut but also in the head (foregut) and thorax (thoracic midgut) areas of the fully engorged dipteran insects. That results in presence of ookinetes and sometimes even initial stages of oocysts' development, throughout the body of blood-sucking insects. However, mature oocysts have been observed only in the midgut.

Sporogony of *Haemoproteus* species developing in biting midges and louse flies is different. The majority of the investigated species of bird hemoproteids develop in biting midges belonging to *Culicoides*. Small oocysts (<20 μm in diameter) with one germinative center and < 100 sporozoites develop in this case (Fig. 3, 6). The average length of sporozoites exceeds 10 μm ; their ends are more or less approximately equally pointed (Fig. 3, 8). Sporogony in biting midges usually completes faster than in 10 days, which is the adjustment to a relatively short (7–10 days) gonadotrophic cycle of the midges. Sporogony of the species developing in louse flies is characterized by a longer development of oocysts (often ≥ 10 days), in which multiple germinative centers and several hundreds of sporozoites are formed (Fig. 3, 7). This type of development, which is not exactly synchronized with blood meal, is an adjustment to the mode of life of relatively long-living louse flies, which spend a long time on birds. The diameter of mature oocysts usually is > 20 μm . For example, oocysts of *Haemoproteus columbae* reach 40 μm or even more in diameter. The average length of sporozoites is usually less than 10 μm ; one end of the sporozoites is more pointed than the other (Fig. 3, 9).

Mature oocysts usually burst, and sporozoites penetrate into the hemocoel of the vectors. Gradual release of sporozoites from oocysts was also observed in several species of *Haemoproteus*.

A part of sporozoites gather in the salivary glands of blood-sucking insects, which become capable to infect birds during their next blood meal.

Distribution

Species of *Haemoproteus* are widespread in birds in countries with temperate and tropical climates. They are absent from high arctic tundra. The diversity of species and their haplotypes is greatest in countries with warm climates, particularly in the tropics. *Haemoproteus* parasites usually are rare in birds on oceanic islands; exceptions are frigate birds and some species of seagulls. The latter two groups of birds are often prevalently infected with hippoboscids transmitted species of *Haemoproteus*. For unclear reasons, *Haemoproteus* parasites have been rarely reported in birds belonging to primitive orders (Sphenisciformes, Gaviiformes, Podicipediformes, Procellariiformes, Tinamiformes, Apterygiformes, Struthioniformes), but they are common and often prevalent among species of evolutionary relatively young orders, particularly of the Passeriformes and also of the Falconiformes, Strigiformes, Anseriformes, Gruiformes, Columbiformes, and Coraciiformes.

Pathogenicity

Pathogenicity in Avian Hosts

The pathogenic impact of *Haemoproteus* parasites on their avian hosts is rather complicated, diverse, but remains insufficiently investigated for the great majority of described species. Many investigated parasites are likely relatively benign for adapted avian hosts. However, there are exceptions. For example, nestlings of the Blackcap *Sylvia atricapilla* infected with *Haemoproteus parabelopolnyi*, which is a widespread parasite in this bird species, lose their weight in comparison to uninfected birds of the same age, but clinical signs or mortality were not seen. Many recent studies have reported reduced survival in wild birds infected with *Haemoproteus* and negative effects of this infection on indices of immunity,

body condition, and reproductive success of their hosts. There is growing evidence for a trade-off between reproductive effort and resistance to parasites, particularly when food resources are limited.

Clinical signs usually are not visible during low-intensity *Haemoproteus* infections but can become evident during acute stage of infections when parasitemias and numbers of tissue meronts reach high intensities. Elevation in numbers of circulating white blood cells (lymphocytes, heterophils, basophils, eosinophils, and monocytes) has been observed during *Haemoproteus* infections. Anemia develops at high parasitemia. During heavy *Haemoproteus columbae* infections the lungs of pigeons are overfilled with meronts, which block the capillaries, resulting in development of pneumonia-like symptoms, which sometimes may cause death of chicks, but adult birds usually tolerate the infection. The inflammatory reaction around meronts often is pronounced. A great amount of insoluble pigment is accumulated in the macrophages of the spleen and liver; these organs obtain black hue.

Development of *Haemoproteus handi* in parrots, *Haemoproteus mansonii* (syn. *Haemoproteus meleagridis*) in turkeys, and some other parasites is accompanied by the formation of huge tissue stages (megameronts) in the endothelial cells of capillaries, in the myofibroblasts of the skeletal muscles (Fig. 3, 4), and in the heart muscle. A capsule-like wall is developed around megameronts; an inflammatory reaction is observed. Rupture of megameronts leads to the formation of large necrotic foci; the myopathy often develops. Calcifications appear in the tissues adjacent to megameronts. *Haemoproteus mansonii* causes hemoprotozoosis in domestic turkeys. Heavily infected birds can perish, while those who survived slowdown in growth and their egg-laying qualities decrease. Megameronts of this parasite develop in the skeletal muscles causing necrosis of the muscular tissues (Fig. 3, 4). Lameness is a characteristic clinical manifestation of the disease in heavily infected birds. The lesions due to megameronts often are grossly visible as white flecks or dark hemorrhagic streaks on the surface of the damaged organs. The myopathy associated with the

development of megalomeronts in the skeletal muscles and heart has been occasionally reported in domestic chickens, but etiology of the chicken infection remains unclear. *Haemoproteus* sp. causes seasonal lethal myopathy in the Pied Currawong *Strepera graculina* in Australia; numerous megalomeronts develop in skeletal, cardiac, and gizzard musculature, but gametocytes appear in the blood only in birds surviving the acute myopathy.

Some widespread species and lineages of *Haemoproteus* spp. are relatively benign in naturally adapted hosts but might cause lethal disease in nonadapted birds. This has been demonstrated in several recent studies in America, Europe, and Australia using a combination of the histopathology and PCR-based methods. However, the true extent of pathology and mortality caused by *Haemoproteus* parasites remains unclear because the severe hemoproteosis and death of infected birds occur mainly during the tissue stage of parasite development, before the appearance of parasitemia. Such abortive infections are difficult to diagnose using blood samples either by microscopy or PCR-based tools because gametocytes are absent from the circulation. Morphologically, the tissue stages of *Haemoproteus* spp. in dead hosts resemble the megalomeronts of *Leucocytozoon* spp. That is why mortality in birds due to unusual pathology in internal organs and muscles was formerly described as an “aberrant *Leucocytozoon* infection.” Recent PCR-based findings indicate that species of *Haemoproteus* are responsible for some instances of mortality in birds. Mortality of captive parrots due to tissue stages of *Haemoproteus minutus* in Europe is an example (Palinauskas et al. 2013). This parasite is widespread and relatively benign in the Common Blackbird *Turdus merula* in Europe, but it kills many species of captive parrots on the stage of megalomeronts, if these birds are exposed to the infection. In the affected parrots, the megalomeronts have been reported in myocardial and skeletal muscles and, to a lesser extent, in the lung and the smooth muscles of the intestinal tract. Parasitemia does not develop, thus the infection is difficult to diagnose using microscopic tools. Due to application of molecular diagnostic

methods, the traditional opinion about the harmlessness and insignificant veterinary importance of avian hemoproteids is ongoing partial reconsideration. *Haemoproteus* parasites are worth more attention in veterinary medicine and in bird conservation projects.

Pathogenicity in Blood-Sucking Insects

Light chronic *Haemoproteus* infections (parasitemia < 0.1 %) are predominant in wild-life; such infections are relatively benign for vectors. However, high *Haemoproteus* infections (parasitemia > 1 %) are also common, particularly during bird breeding seasons; such infections are virulent both in coevolved and not coevolved vector-parasite associations. The life span of blood-sucking insects is inversely proportional to the intensity of gametocytemia in birds, on which they feed. Mortality rate of biting midges fed on heavily infected birds is usually high. Recent studies indicate that *Haemoproteus* infections negatively influence fitness of louse flies and biting midges.

It is important to note that *Haemoproteus* parasites cannot complete sporogony in mosquitoes (Culicidae), but they are virulent for the bird-biting mosquitoes, which rapidly die after feeding on heavily infected blood meals. *Haemoproteus* infections are more virulent to mosquitoes than *Plasmodium* infections. Exposed mosquitoes die due to numerous ookinetes, which develop throughout entire digestive tracts of fully engorged insects, including the head (foregut) and thorax (thoracic midgut) soon after the exposure; this is not a case during *Plasmodium* infections. Ookinetes of *Haemoproteus* parasites find no barrier in their way from gut contents to the adjacent tissues of the head and thorax; these parasites cause marked physical damage throughout the body of the mosquitoes. That contributes to high virulence of *Haemoproteus* parasites in blood-sucking insects.

Diagnosis

A combination of the microscopic examination of Giemsa-stained thin blood smears and the

polymerase chain reaction (PCR)-based methods is the gold standard. The PCR-based diagnostic methods using general primers are sensitive in the detection of light parasitemia and the identification of species, particularly on tissue stages. However, this tool markedly underestimates coinfections of parasites belonging to the same and different genera of hemoproteids and also *Plasmodium* spp.; microscopic examination of blood films helps to minimize this shortcoming of the molecular detection.

Immunity

Virtually nothing is known about immune mechanisms in hemoproteid infections. Domestic pigeons with chronic parasitemia of *H. columbae* acquire immunity (premunition) which is being lost while gametocytes disappear from the blood. Widespread coinfections of different species of *Haemoproteus* indicate that a cross immunity does not develop.

Prevention and Treatment

Prevention is based on the protection of birds from bites of vectors during periods when blood-sucking dipteran insects are abundant and active (usually the rainy warm seasons of a year). Small groups of birds or expensive individuals are put in cages or aviaries covered with fine-mesh bolting silk (a mosquito-net effect); that prevents birds from bites of vectors. Treatment has been insufficiently developed. Atebrine, plasmochin, chloroquine sulfate, primaquine, mefloquine, and buparvaquone are effective for reducing parasitemia, but these drugs usually do not affect tissue stages.

Acknowledgments G. Valkiūnas is grateful to C. T. Atkinson for providing preparations of megalomerozoites of *Haemoproteus mansonii* and T. A. Iezhova for technical assistance during preparation of the illustration plates in chapter *Haemoproteus*.

Haemoproteus: Species Relations

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The paper of Matta et al. (2014) shows the phylogenetic relationships of more than 50 species of the genus *Haemoproteus* and compares them with four *Leucocytozoon* species. All of them are blood parasites of birds (waterfowls, ducks, Passeriformes, etc.). Those of Passeriformes turned out to represent a monophyletic group.

Haemosporidia

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This group of protozoan parasites belongs to the second suborder Haemosporina within the order Schizococcidia. They have a heteroxenous life cycle involving vertebrates (where merogony = schizogony occurs and gamogony is initiated) and bloodsucking vectors (insects, wherein syngamy and sporogony proceed). Their motile stages have developed similar organelles (except for the lacking conoid) like the members of first suborder (Eimeriina) of the Schizococcidia. The Haemosporidia include the genera ► *Plasmodium*, *Leucocytozoon*, and *Haemotoproteus*, while the sister group ► *Piroplasmea* comprises among others the genera ► *Babesia* and ► *Theileria*.

The members of the Haemosporidia parasitize in erythrocytes of their hosts and are enclosed in a so-called ► *parasitophorous vacuole*. This vacuole is also present around just penetrated merozoites of *Babesia* and *Theileria* species, but degenerates after a short time.

Hairworms

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

English trivial name for ► *Capillaria* species of humans and animals.

Halicephalobus

Name

Greek: *hyalinus* = transparent, clear, *kephalon* = head, *lobos* = lobe.

Synonyms

Micronema.

General Information

Genus of free-living ► *nematodes* of the family *Cephalobidae*, which are related to the members of ► *Rhabditidae*. Some species such as *H. delectrix* (Latin: *delectio* = destruction), however, are able to penetrate the skin of vertebrates or enter them via food (as larvae or adults). The described, fully proven cases include horses, cattle, rabbits, and (even more rare) humans. In horses, brain, lung, ocular, and renal infections, granulomatous posthitis are described, while mastitis was found in addition, in cattle. Another species of horses is *H. gingivalis*. Up to now only females were found reaching a length of only 0.5 mm, while the larvae on the soil reach 120–220 µm, when hatching from the 40 × 12 µm sized eggs. All stages possess a rhabdoid oesophagus.

Therapy

Ivermectin, Nematocidal Drugs.

Haller's Organ

Housing some of the tick's olfactory chemoreceptors, it is part of the sensory structures on the

Haller's Organ, Fig. 1 SEM of the first right leg of *Ixodes ricinus* showing the external structures of the Haller's organ (H) and one claw (C) and the pulvillus (P)

Haller's Organ, Fig. 2 Diagrammatic representation of the arrangement of the sensilla in the Haller's organ of an ixodid (Redrawn and modified after Sonenshein 1991). A axons, AP anterior dorsal pit, CA capsular sensillum, CP capsular aperture, DS distal precapsular sensillum, G gland, GA gland's aperture, GR grooved sensillum, GU gustatory hair, MP multiporose sensillum, RN receptor neurons, SP sensilla of posterior capsule

dorsal surface of the tarsi on leg one of ► ticks (Fig. 1, ► [Ticks/Host Recognition](#)).

This organ (Figs. 1 and 2) consists of several units:

1. **Posterior capsule:** except for *Ixodes ricinus* and a few others it is covered and exposed only via a small slit.

2. **Anterior pit,** which represents a depression located distal to the posterior capsule, surrounded by a cuticular fold and containing a small number of sensilla.

Small groups of olfactory sensilla (slightly posterior to the capsule and distal to the anterior capsule) apparently also function in the same way as the sensilla of the Haller's organ (Figs. 1 and 2).

The composition and number of the sensilla involved are genus- and species-specific, thus explaining that different ticks react differently onto host attractants and repellents.

Halteres

Heinz Mehlhorn

Ancient name for the sausage-shaped gamonts of ► [Haemoproteus species](#).

Halzoun Syndrome

Disease in humans due to infection with the dog pentastomid worm ► [Linguatula serrata](#), which

Halzoun Syndrome, Fig. 1 LM of a pentastomid worm (*Linguatula*)

block the nasal pathways and may thus introduce ► **oedema** and unfeelingness of head regions.

Main clinical symptoms: Oedema, disturbances of organs.

Incubation period: 7 days to months.

Prepatent period: 6–7 months.

Patent period: 15 months.

Diagnosis: Microscopic determination of worm eggs in nasal mucus (Fig. 1).

Prophylaxis: Avoid contact with dogs in tropical regions.

Therapy: Provocation of sneezing, mechanical withdrawal of the worms.

Hamilton and Zuk Hypothesis

In 1982, Hamilton and Zuk published a paper whose consequences in the world of parasitologists and ecologists were considerable. It is well known that, in certain animal species, there is a

marked dimorphism in size, ornamentation, and colours between males and females. This is the case especially in birds (although not only in them), where males are often brightly coloured and compete for females through complicated parades. Darwin explained ► **sexual dimorphism** by natural selection: if there is a genetic diversity in, for instance, the length of feathers in males, and if females mate preferentially (sexual selection) with the males which have the longest feathers, then the genes responsible for long feathers increase their frequency in the population. If the genetic diversity of feather length is continually renewed, there is a runaway process which leads to extravagant ornamentation like that of pheasants and paradise birds.

This explains the possible mechanism of sexual selection, but it does not say why sexual selection exists. There are at least two difficulties: one is that these processes do not exist in all species (for instance, male and female magpies and many other birds look the same); another is that a price has to be paid for extravagant ornamentation (there is a metabolic price for constructing them and the bright colours make birds more prone to predation).

The Hamilton and Zuk hypothesis states that the brightness of colours and the quality of parades provide females with an indication of the “quality” of males, especially of their ability to resist parasites. The idea is that, if the male of a given species is brightly coloured, it may develop these colours fully only if it possesses resistance genes to parasites. The “interest” of the female to mate with such a resistant male is to associate her own genes with “good genes,” thus giving her offspring the best chance of survival. If the hypothesis is correct, there must be a positive correlation between the mean parasite load of a species and the degree of sexual dimorphism. Since Hamilton and Zuk published their article, a number of studies (comparative analyses and experiments) have tried to confirm or to contradict the hypothesis. Logically, the more a species harbours parasites, the more the cost of extravagant colours and ornamentation is compensated by the

benefits of sexual selection. In other words, being bright and colourful is meaningful only if selection of resistance genes is necessary.

The hypothesis has been the subject of many controversies, some authors being very negative. More than 20 years after the publication of Hamilton and Zuk's article, it seems that a majority of surveys and comparative analyses demonstrate that the hypothesis is at least partly correct.

Hanging Groin

Symptom due to infection with ► [Onchocerca](#) worms. Chronically enlarged lymph nodes may introduce a “mild local elephantiasis” due to superficial water influx.

Hannemannia

Genus of mites of amphibia.

Haplobothriidae

Family of cestodes in freshwater fish (e.g., genus *Haplobothrium globuliforme* of bowfin = *Amia calva*). These species are unique because they appear as intermediate forms between ► [Pseudophyllidea](#) and ► [Trypanorhyncha](#), since their bothria are located at the tips of four tentacle-like projections known as proboscides.

Haplometra cylindracea

This is a rather common plagiorchiid digenetic trematode in the lungs of frogs already known since 1800 (cf. ► [Paragonimus](#) species of humans).

Haplorchis

Genus of trematode flukes of the family Heterophyidae, which rarely may also occur in the intestine of humans ► [Heterophyes](#).

Haplosporidia

Group of parasites probably belonging to a known phylum of Protozoa, mostly parasitizing clams (e.g., *Haplosporidium armoricatum* = *Minchinia armoricana* is found in clams such as *Ostrea edulis*). Recently they were included into protozoan phylum ► [Alveolata](#).

Haplosporidium

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of the so-called Ascetosporea. *Haplosporidium* species parasitize in mollusks and in decapod crustaceans.

Haplosporidium nelsoni

Microsporidian of the American oyster, formerly named MSX-body.

Haptyrhynchus

H. nidulans (syn. *Sarcopterynus nidulans*) is a small mite that lives inside the feather shaft of doves and other birds (Fig. 1) ► [Syringophilus](#).

Haptyrhynchus, Fig. 1 Adult male of *H. nidulans* (syn. *Sarcopterynus*)

Harara

Hard Ticks

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

These ticks belong to the family ► [Ixodidae](#) (► [ticks](#)). They received their name because they have a dorsal scutum in all developmental stages (larva, nymphs, ♀ and ♂ adults). In males, this scutum covers the whole dorsal side.

Hartmanella

Genus of opportunistic ► [amoebae](#). *Hartmannella vermiformis* caused several human cases of fatal central nerve system disease.

HAT

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Abbreviation for human African trypanosomiasis. The agents of disease (*Trypanosoma brucei gambiense* and *T. b. rhodesiense*) are transmitted by bites of infected ► [Glossina](#) flies. Recently there are five medicaments registered that are used to treat this disease. However, all are imperfect and may initiate considerable side effects due to their toxicity.

Suramin (Germanin, B-205) is the oldest anti-HAT drug currently still in use which was developed by Bayer AG (Germany) basing on naphthalene urea and on early works of ► [Paul Ehrlich](#), the founder of “chemiotherapy” around 1900. The most “modern” anti-HAT medicaments were detected in the 1980s, when the compound eflornithine was introduced, that is today used in combination with nifurtimox. However, although some promising orally administrable new compounds are now (2014) in the early clinical testing phase, treatment of HAT is far from being solved.

Excretion system of nematodes consists of a single cell, which forms two longitudinal channels

Heartwater

The significance of some rickettsial diseases is difficult to assess. This applies particularly to heartwater, a disease of domestic ruminants caused by ► [Cowdria](#) (syn. [Ehrlichia](#)) [ruminantium](#), which is transmitted by all African

H-Cell, Fig. 1 Diagrammatic representation of the H-cells of some genera of nematodes

species of ► *Amblyomma* found on susceptible hosts. Experimentally, it is also transmitted by the American *A. maculatum*, too, and the disease's recently discovered presence on Guadeloupe and other Caribbean islands (where *A. variegatum* has been introduced from Africa) poses a severe threat to the cattle and sheep industries in tropical and subtropical mainland America. Heartwater is an acute disease in susceptible animals such as introduced *Bos taurus* cattle but is less apparent in endemic situations which exist in most of sub-Saharan Africa. After an ► [incubation period](#) of 1–5 weeks following the bite of an infected tick, the first clinical signs are a rise in temperature to over 40°C; in many cases, few other signs appear until shortly before death. Hypersensitivity and other nervous symptoms appear during the latter stages of the disease, culminating in central nervous effects. Many animals recover without showing any symptoms beyond fever. Definitive diagnosis is usually only possible at post mortem by demonstrating the causative organism in Giemsa-stained smears of brain tissues. Gross lesions commonly seen are pulmonary oedema, hydropericardium (from which the disease has its name), hydrothorax, and ascites. The mode of transmission may be through

regurgitation of the midgut contents by the tick, but this has not been demonstrated. A crude and fairly inefficient form of immunization is available.

Therapy

Treatment is possible through tetracyclines, but frequently not practically possible because of inadequate diagnostic resources.

Heartworm

Synonyms

Dirofilaria immitis.

Disease

Heartworms: Treatment of Dogs

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The mosquito-transmitted heartworm of dogs (*Dirofilaria immitis*) can be treated; however, it is rather complicated. The following scheme is one of several possibilities:

Day 0: Diagnosis with the help of antigen test.

Day 1: Start with macrocyclic lactones.

Days 1–28: Doxycycline (10 mg/kg bodyweight).

Day 30: Macrocyclic lactones.

Day 60: Macrocyclic lactones, plus first injection with melarsomine (2.5 mg/kg bodyweight, intramuscularly).

Day 90: Second injection with melarsomine.

Day 91: Third injection with melarsomine + cortisone in cases of high-level infection.

Day 120: Test for microfilariae; if the test is positive, further treatment is needed.

Day 270: Antibody test.

Helminth

Synonyms

Worm, from Greek: *helminthos*.

Annelida, Acanthocephala, Platyhelminthes, Cestodes, Trematodes, Nematodes, Pentastomida, Leeches.

Helminthic Infections, Pathologic Reactions

Lesions and inflammatory reactions accompanying ► [helminth](#) infections are particularly

complex and variable. Immunity against these large organisms is generally less effective than against protozoans and part of a worm's life cycle may be spent in an immunologically privileged state, as with the adult schistosomes, or in a privileged site, as with the helminths living in the lumen of the intestine. Because of the more prolonged infections with schistosomes, and the release of eggs over a long period of time, the histologic reaction to a recently arrived egg can often be seen side by side with reactions to eggs that have been present for a long time as shown by granulomas destroyed eggs and fibrosing (► [Pathology](#)/Fig. 1a–d). One of the hallmarks of the defense against helminths is the eosinophilic granulocyte which is toxic to many worms. This is accompanied by an acidic lysophospholipase of a molecular weight of 13,000 with a free sulfhydryl group which may crystallize as Charcot-Leyden crystals (► [Pathology](#)/Fig. 3b). These crystals have been obtained not only from eosinophils but also from basophils. The role of the latter cells has been studied less frequently than that of the eosinophils. Because basophils and tissue mast cells require special staining for their demonstration, such as Alcian blue at pH 0.5, and are not shown on routine histologic sections, little is known of the role of basophils in the inflammatory and possibly defensive reaction against helminths. More information is available about their participation in the inflammatory reaction evoked by ► [ticks](#).

Helminths Using Polychaetes as Hosts

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Many species of nematodes and platyhelminthes use polychaetes as intermediate hosts. For details see People (2013).

Figures 1 and 2.

Structures

Figure 3.

Hem(oglobin) Interaction, Fig. 1 Model of the formation of the noncovalent heme-chloroquine complex (Gutteridge 1993)

Artemisinin and -Derivatives

Important Compounds

Dihydroartemisinin, Artemether, Arteether, Artesunate, Bicyclic trioxanes, Tetraoxanes, Tricyclic trioxanes, 11-alkyl,12-deoxy artemisinins, Arteflene.

Synonyms

Artemisinin: Qinghaosu.

Combination: Artemether/Lumefantrine (Riamet[®], Coartem[®]).

Clinical Relevance

Artemisinin has been used so far for the treatment of malaria in at least three million people. The advantage of this drug is its rapid action against cerebral malaria (“► [Malaria](#)”).

Artemisinin is isolated from the plant *Artemisia annua* and was originally developed in China. It is chemically related to 1,2,4-trioxanes. Among artemisinin and the so-called first generation compounds are esters or ethers obtained from the lactol, dihydroartemisinin.

The rediscovery of quinghaosu (artemisinin) in China in 1972 and the subsequent synthesis of artemether and artesunate have provided highly

Hem(oglobin) Interaction, Fig. 2 Action of antimalarial drugs on life cycle stages. For life cycle details see the legend “► *Plasmodium*,” Fig. 2

effective alternatives to quinine. The artemisinin derivatives are today the most rapidly acting and potent of all the antimalarial drugs. They can be given once daily and are safer and easier to administer than quinine. Artesunate or artemether given orally are an essential component of the combination treatment of uncomplicated falciparum malaria, which is now accepted as the treatment of choice. In the treatment of severe malaria, intravenous artesunate is more rapidly acting in terms of parasite clearance and simpler to administer compared to quinine. Mortality on artesunate recipients was 15 % compared to 22 % in quinine

recipients with severe malaria. In addition, artesunate treatment was well tolerated, while quinine treatment was accompanied with hypoglycaemia. The combination artemether/lumefantrine (Riamet[®], Coartem[®]) is not suitable for prophylaxis but is recommended for stand-by self-medication. The dosage is 80 mg/ 480 mg (=4 tablets) initially, followed by further 4 tablets after 8 h, and 4 tablets two-times daily on days 2 and 3 (in total 24 tablets).

The antischistosomal effect of artemether and other artemisinin derivatives has been described in the 1980s. During 1994 and 1996 seven large-

Hem(oglobin) Interaction, Fig. 3 Structures of antiparasitic drugs affecting hem degradation

scale clinical trials had been conducted in China showing 85 % protection against *Schistosoma japonicum* infections, if the drug is taken every 2 weeks starting before the first contact with water containing infected snails. Thus, artemether can be used for prophylaxis against schistosome infections (“► [Membrane-Function-Disturbing](#)

[Drugs,”](#) Table 2). Effects against *S. mansoni* and *S. hematobium* infections have been shown in laboratory experiments. Successful clinical trials against these two species have been conducted in Africa in the late 1990s. The combination of praziquantel and artemether would be effective against all stages of schistosomes. Praziquantel

acts primarily against adult worms and artemether against juvenile stages. This approach is in clinical trial in China, Egypt, and the Philippines.

Molecular Interactions

Artemisinin is characterized by its new structure and new mode of action unrelated to any other known antimalarial drug. Indeed, there is no cross-resistance against any of the known antimalarials. The activity of artemisinin and its derivatives is directed only against erythrocytic schizonts (Fig. 2). High drug concentrations are detectable in the region of membranes of intraerythrocytic ► [trophozoites](#). There are also other measurable artemisinin-induced metabolic alterations: an interference with the energy production, a reduction of DNA synthesis, an inhibition of mRNA polymerase activity, and an inhibition of purine synthesis in *Plasmodium berghei* at the level of inosine monophosphate dehydrogenase.

The mode of action proceeds in two different steps. In the first step the endoperoxide bridge is cleaved (Fig. 4). This reaction is catalyzed by intraparasitic iron and heme, and leads to the generation of unstable free radical intermediates. The selective toxicity of artemisinin against malaria parasites is presumably due to this iron catalyzed generation of free radicals, and this is favored by the fact that just these intraerythrocytic parasitic stages are rich in iron and heme. In the second step of the reaction, specific malaria proteins with molecular masses of 25, 32, 42, 50, 65, and >200 kDa become alkylated. These alkylation reactions take place in parasitic ring forms and trophozoites. Proteins of uninfected red blood cells or of infected red blood cells pretreated with the inactive derivative desoxyarteether are not alkylated. Structure activity relationships of various tricyclic trioxanes reveal that certain rings in artemisinin are redundant. Thus, the high artemisinin-like activity is due to the structurally minimal bicyclic trioxane. A rapid rearrangement of active bicyclic trioxanes and spirocylane ring is induced by ferrous chloride.

It was recently reported that artemisinin may be involved in specific inhibition of plasmodial

cysteine protease activity responsible for about 30 % of hemoglobin degradation by *Plasmodium yoelii*.

Resistance

So far there are no reports about resistance against artemisinin or its derivatives. However, the clinical trials of artemether and artemether-benflumetol have led to the observation that artemisinin is able to induce drug metabolizing enzyme and, thus, may contribute to its own clearance.

Amodiaquine

Synonyms

4-((7-chloro-4-quinolinyl)amino)-a-(diethylamino)-o-cresol, SN10751.

Clinical Relevance

Amodiaquine was invented between 1941 and 1945 as an antimalarial drug and was introduced in 1975. Its antimalarial activity is comparable to that of chloroquine.

Molecular Interactions

Amodiaquine is a member of the 4-aminoquinolines with an activity which is directed against erythrocytic schizonts and gametocytes of plasmodia (Fig. 2). Amodiaquine serves as a prodrug, which is converted to desethylamodiaquine responsible for the antimalarial activity. The mechanism of action is presumably identical to that of chloroquine (Fig. 1).

Resistance

The mechanism of resistance against amodiaquine is also presumably identical to that against chloroquine which is assumed to be due to an impaired uptake mechanism. This is supported by the appearance of a general cross-resistance between amodiaquine and chloroquine. There are also a few hints of amodiaquine activity against chloroquine-resistant ► [Plasmodium](#) strains but in general resistance with this drug is no problem.

Hem(oglobin) Interaction, Fig. 4 Cleavage of the Endoperoxide Bridge of Artemisinin by Hem-Iron (Meshnick et al. 1996)

Halofantrine

Clinical Relevance

Halofantrine was developed within the Walter Reed Army Institute for Research (WRAIR) anti-malarial drug development program in 1984. It had been introduced in 1988. However, because of severe cardiovascular side effects, halofantrine is no longer used. The antimalarial activity against *Plasmodium falciparum* and *P. vivax* is much better documented than that against *P. malariae* and *P. ovale*.

Molecular Interactions

Halofantrine is a phenanthrene methanol, and its activity is directed against erythrocytic schizonts (Fig. 2). The action of halofantrine on the molecular level is unknown. It is presumably different from that of quinine and mefloquine, but it may be otherwise similar to that of mefloquine (Fig. 1).

Resistance

First reports on resistance appeared in 1992. In Thailand there are mefloquine-resistant strains of *P. falciparum* which show simultaneously reduced sensitivity to halofantrine, thus indicating cross-resistance between mefloquine and halofantrine. On the molecular level, the resistance mechanism against halofantrine is suggested to be of the MDR phenotype similar to that against mefloquine and quinine, while it may be different from that against chloroquine.

Chloroquine

Synonyms

7-chloro-4-(4-diethylamino-1-methylbutylamino)quinoline, SN71374, RP3377, Aralen, Nivaquine B, Sanoquin, Artrichin, Bipiquin, Reumachlor, Bemaphate, Resoquin, Resochin, Chlorochin.

Clinical Relevance

Chloroquine has been used in the treatment of malaria for some 60 years since its discovery in the 1930s. It exerts a wide variety of activities against different parasites.

The activity of chloroquine against ► *Entamoeba histolytica* is directed only against liver abscesses. It has no effect against intestinal stages. Chloroquine especially is used in combination with emetine to improve the curative effects of the latter. Other combinations with significant amoebicidal activity are chloroquine/dehydroemetine or chloroquine/diloxanide furamide.

As antimalarial drug chloroquine is mostly used as a diphosphate salt. It is effective against all four human malaria parasites. Thus, it has high activity against blood schizonts (asexual intraerythrocytic stages of *Plasmodium vivax* and *P. falciparum*) and against gamonts of *P. vivax* (Fig. 2). It has no significant effects against extraerythrocytic stages in the liver. Therefore, chloroquine cannot be used as a causal-prophylactic drug.

Molecular Interactions

The amoebicidal action of chloroquine is directed against trophozoites (magna forms) in the liver and other extraintestinal organs. The precise mechanism of action in ► *amoebiasis* is unknown. Presumably it is different from the antimalarial action by intercalation into DNA or by inhibition of protein-synthesis.

There are different hypotheses for the mode of action of chloroquine. The uptake of host-derived hemoglobin and its digestion in the food vacuole by developing parasites plays a vital role in survival of these parasites, and this is therefore the Achilles' heel, which makes the plasmodia vulnerable to quinoline compounds. During the degradation of globin ferrous heme is released and oxidized to a ferric form, which is toxic for the parasites by damaging parasitic membranes and inhibiting various parasitic enzymes including proteases. To circumvent these toxic effects of ferrous heme plasmodia have evolved specific

detoxification mechanisms. These rely on the conversion of the ferric hem into an insoluble, unreactive crystalline material called ► *hemozoin* (= malaria pigment). Hemozoin is a polymer of the iron porphyrin ferriprotoporphyrin IX (hemin) residues linked by iron-carboxylate bonding β -haematin. It is at present controversial, whether the formation of this polymer is catalyzed by a heme polymerase or proceeds spontaneously without protein. Despite these differences there is no doubt that just this important polymerization step is susceptible to inhibition by quinoline-containing antimalarial drugs (chloroquine, quinine, amodiaquine), Fig. 1. This is supported by a strong correlation among a series of quinoline compounds between inhibition of parasite growth and inhibition of the heme polymerization. In addition, the subcellular localization of the inhibition of heme polymerization correlates with the site of drug accumulation. Thereby, the heme substrate is probably converted into a noncovalent complex with the quinoline. This hemin-chloroquine-complex is assumed to be toxic to the parasite by lysing membranes or by inhibiting further aspartic protease-mediated hemoglobin degradation.

In the alternative model of chloroquine action by Warhurst (1995), in which the presence of a heme polymerase is not necessary for β -hematin formation, the formation of β -hematin can be inhibited by chloroquine, amodiaquine, and quinine just as they are reported to inhibit heme polymerase. The action of blood schizontocides is thus, according to this model, simply by binding to hemin monomers and preventing their polymerization and detoxification by sequestration with apohemozoin.

For all the known models of the chloroquine action it is proposed that the drug is taken up by the parasites by passive diffusion. However, recently a chloroquine-transporter in the plasma membrane of *P. falciparum* could be characterized. This transport protein is responsible for the accumulation of drug inside the parasite. The uptake mechanism is temperature-dependent, saturable, can be inhibited and follows the

Michaelis-Menten kinetics in contrast to the chloroquine uptake into noninfected erythrocytes, which is by simple diffusion. It is proposed that the chloroquine-transporter works as a Na^+/H^+ -exchange protein and is able to regulate the cytoplasmic pH. In contrast to other [eukaryotes](#) *P. falciparum* appears not to possess other pH-regulatory systems beside this exchange protein. This is obviously an adaptation to the intracellular parasitism and may explain why this system is an Achilles' heel by which the plasmodia become vulnerable to the action of quinolones. Corresponding exchange proteins from human cells do not bind or transport chloroquine. The energy for this process is gained via the Na^+ -gradient which is built by the Na^+/K^+ -ATPase. Chloroquine is able to stimulate the exchange protein, thus leading to an enhanced exchange of protons and Na^+ -ions. As a result, pH and Na^+ -ions are enhanced intracellularly and chloroquine is taken up and accumulated during the initial activation phase. The chloroquine uptake proceeds as long as there is a Na^+ -gradient across the plasma membrane. The molecular mechanism of the activatory effect of chloroquine is unclear at present.

Besides the amoebicidal and antimalarial activity, chloroquine has also antibabesial and anticestodal activities. The mechanism of action of chloroquine in these indications is not yet known. In other nonparasitic indications chloroquine is used in rheumatoid arthritis, chronic polyarthritis and Lupus erythematoses. Here the membrane-stabilizing-effects of chloroquine may contribute to the anti-inflammatory effects. Thereby, the actions of lysosomal proteases become inhibited by this drug.

Resistance

Chloroquine resistance in *P. falciparum* was first observed in 1957. The greatest hindrance for the elucidation of the resistance mechanism was lack of knowledge of the mode of action of the quinoline-based antimalarials on *Plasmodium* spp., which is still discussed controversially. In chloroquine-resistant *P. falciparum* the release of

chloroquine is 40–50 times more rapid compared to wild-type strains. The efflux rates of chloroquine are different between sensitive and resistant strains. The accelerated chloroquine efflux in resistant strains can be inhibited by calcium-channel blocking agents such as verapamil. Thus, the chloroquine-resistance mechanism resembles that of multidrug-resistant cancer cells. Two genes in *P. falciparum*, *pfmdr1* and *pfmdr2*, could be identified, which are homologous to MDR genes. The gene *pfmdr1* encodes a 162 kDa homologue of the P-glycoprotein (Pgh1), located mainly at the membrane of the digestive vacuole of the parasite. Indeed, there is evidence for the involvement of Pgh1 in nucleotide-dependent transport across membranes. However, a correlation between amplification of *pfmdr1* and chloroquine resistance remains doubtful.

In an alternative hypothesis, chloroquine-resistance may be linked to an impaired chloroquine-uptake mechanism. Indeed, it could be shown recently that resistant *P. falciparum* strains possess an altered Na^+/H^+ -exchange protein which are continuously in an activated state, so that chloroquine cannot activate it furthermore. As a result, chloroquine cannot be taken up and accumulated by these cells. The molecular biological background for the constitutive activation of the exchange protein in resistant cells is, however, unclear to date.

Quinine

Synonyms

6-methoxy-a-(5-vinyl-2-quinuclidinyl)-4-quinolinemethanol, Aristochin, Aristochin, Aristochin, Aristochin, Biquinate, Coco-Quinine, Dentojel, Diquine carbonate, Quinamin, Quinamm, Quinate, Quinbisan, Quine, Quinoform, Quinsan, Quiphile, Tasteless Quinine.

Clinical Relevance

Quinine is the main alkaloid of the Cinchona bark in Peru known as effective febrifuge against

intermittent fever since the early seventeenth century. It has some activity against *Trypanosoma brucei*, but the main activity relies on the antimalarial activity. It is used especially for the therapy of chloroquine- and multidrug-resistant *Plasmodium falciparum* infections. The combination with tetracyclin is used in cases of severe resistance. Furthermore, quinine is used in combination with clindamycin against babesiosis. Another, nonparasitic indication is the usage as antiarrhythmic drug.

Molecular Interactions

The activity of quinine is directed against erythrocytic schizonts and gametocytes of all human *Plasmodium* spp., but gamonts of *P. malariae*, *P. ovale*, and *P. vivax* are also damaged (Fig. 2). The action of quinine on the molecular level is suggested to be identical to that of chloroquine (Fig. 1).

Resistance

Quinine has been used in the meantime for more than 350 years without losing its general effectiveness. Formerly quinine was, however, probably never used at a high enough frequency against *P. falciparum* to induce resistance. The existence of cases of quinine resistance was reported for the first time in 1910 by Nocht and Werner in Brazil. The molecular basis of the mechanism of quinine resistance is assumed to be identical to that of mefloquine, but different from that of chloroquine.

Mefloquine

Synonyms

Larian, Laricur.

Clinical Relevance

Mefloquine was synthesized in 1971 and marketed since 1977. The activity is directed against chloroquine-resistant and mostly against multidrug-resistant *Plasmodium falciparum*.

Mefloquine acts against the erythrocytic schizonts of all 4 *Plasmodium* spp. (Fig. 2). It has

additional activity against young gamonts of *P. malariae*, *P. ovale* and *P. vivax*.

Molecular Interactions

The mechanism of action of mefloquine may be similar to that of chloroquine or quinine, since mefloquine and chloroquine are believed to share the same drug receptor within the food vacuole of infected erythrocyte (Fig. 1). However, in contrast to chloroquine which has been shown to inhibit the activity of the hem polymerization by more than 80 %, mefloquine does not cause such an inhibitory effect. There is another hypothesis that the antimalarial activity of mefloquine may be due to an interaction with parasite proteins by hydrogen-bond formation.

Resistance

There is occasional resistance against mefloquine. The first case of mefloquine resistance was reported in Thailand in 1982. In the meantime cure rates from eastern Thailand are reported to have dropped to only 41 %. The molecular basis of resistance against mefloquine is presumably different from chloroquine resistance since mefloquine still exerts activity against chloroquine-resistant *P. falciparum*. Enhanced drug efflux as seen in chloroquine-resistant *P. falciparum* has not yet been shown with the class of the structurally related compounds mefloquine, halofantrine, and quinine. The neuroleptic agent and calcium-channel-blocker penfluridol increases the susceptibility of mefloquine-resistant strains to mefloquine, and interestingly, there is no increase of mefloquine-activity in mefloquine-resistant strains by verapamil. By contrast penfluridol cannot increase the susceptibility against chloroquine in chloroquine-resistant strains of *P. falciparum*. Mefloquine resistance exhibits patterns more indicative of the MDR phenotype and is often associated with halofantrine and quinine resistance. The EC₅₀ values for mefloquine, halofantrine, and artemisinin are decreased by penfluridol, but not by agents modulating chloroquine resistance. There are several reports on an association between mefloquine resistance and amplification of pfmdr1. Thus, a mefloquine-

resistant clone selected by drug pressure exhibited a two- to four-fold increase in the copy number of *pfmdr1* and a significantly higher level of corresponding mRNA compared to the sensitive clone. In 10 mefloquine-resistant strains with concurrently reduced susceptibility to halofantrine, *pfmdr1* is present in multiple copies, whereas this amplification is not found in the only sensitive strain. A selection for mefloquine resistance in 2 clones generated amplification and overexpression of *pfmdr1* and overexpression of its product, Pgh1. The overexpression of Pgh1 correlates with increased resistance to halofantrine and quinine and decreased resistance to chloroquine. Thus, there seems to be an inverse correlation concerning Pgh1 expression in chloroquine resistance and a MDR phenotype involving mefloquine, halofantrine, and quinine.

Lumefantrine

Synonyms

Benflumetol; Combination: artemether/lumefantrine (Riamet[®], Coartem[®]).

Clinical Relevance

Lumefantrine is used in the drug combination with artemether and recommended for standby medication in uncomplicated malaria tropica.

Molecular Interactions

It is shown that lumefantrine interacts with synthetic phospholipid bilayers of dipalmitoyl- or dioleoylphosphatidylcholine, egg lecithin or mouse erythrocyte membranes, thereby provoking a condensing effect. Artemether and lumefantrine are shown to act synergistically against *P. falciparum* in vitro.

Resistance

The drug combination is active against multiresistant *Plasmodium* strains under field conditions.

Hematuria

Name

Greek: *haima* = blood, *uron* = urin.

Symptom of infection with ► *Schistosoma haematobium*, ► pathology.

Heme

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek: *haima* = blood.

This compound colors the red blood cells (erythrocytes).

Hemelytron

Forewing of Heteroptera (bugs) consisting of a hard and membranous (hind) region.

Hemiclepsis Marginata

Leech that reaches a length of up to 3 cm, sucks at the surface of fishes. Its mouth sucker is heart-shaped (upside down).

Hemidesmosome

Asymmetric (half-side) arrangement of desmosomes to be used for attachment of cells at different surfaces (e.g., ► [undulating membrane](#) of trypanosomes).

Hemimetabolous Development

In some orders of parasitic insects (e.g., ► [lice](#), ► [bugs](#)) the larvae hatching from eggs are very similar to the adults (► [Imago](#)) except for the absence of functional gonads and wings, if these are present at all in adults (► [Bugs](#)/Fig. 1, ► [Lice](#)/Fig. 2). Furthermore these types of larval instars, which are generally called nymphs, feed mostly in the same way as the adults. During growth several molts (► [Ecdysis](#)) occur, the number of which varies between species. The last ► [ecdysis](#) during this gradual development leads to mature and fertile adults, which soon start reproduction.

Hemiptera

Synonyms

Bugs, Rhynchota.

Hemoglobin C

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This variation occurs in several human African populations, where the β -globin-chain bears at the position 6 lysine instead of glutamate. This mutation protects humans being either homo- or heterozygotes (with respect to this variation) from severe malaria.

Hemoglobinopathies

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Several common Mendelian hemoglobinopathies have side effects in protecting humans (especially children) from early death due to *Plasmodium falciparum* malaria: ► [Sickle cell](#) disease, α and β thalassemia, as well as glucose-6-phosphate

dehydrogenase deficiency or ► [possessing of hemoglobin C](#).

Hemolysis

Lysis of red blood cells, symptom of infection with ► [Babesia](#) species.

Hemoptysis

Sputum contains blood due to lung lesion in ► [Paragonimus](#) infections and/or tuberculosis.

Hemorrhagia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: haima = blood; rhagia = opening.

This term describes an inner or outer bleeding, e.g., due to attached parasites such as ► [hook-worms](#) or ticks, etc.

Hemorrhagic Effects

From Greek: *rhegnymie* = disrupt. Symptom of many parasitosis, when blood vessels become destroyed; e.g., sarcosporidiosis.

Hemozoin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Hemozoin (malaria pigment, β -hematin) is the chemically inert crystalline substance produced in the digestive food vacuole of blood-stage malaria parasites. The pigment is visible microscopically in intraerythrocytic stages that are actively degrading hemoglobin. During proteolysis of host erythrocyte hemoglobin, monomeric, toxic heme is released. In order to protect itself, the malaria parasite has evolved a distinct mechanism for detoxification of free heme through its conversion to insoluble and chemically inert β -hematin crystals called hemozoin. Hemozoin is a dark-brown pigment made of dimers of heme molecules. The mechanism of hemozoin formation is still not well understood. Recent data suggest that in blood-stage malaria parasites, a multiproteinase complex, together with a heme detoxification protein, may mediate the formation of the pigment from heme. Hemozoin is also formed as a detoxification product of hemoglobin digestion in a variety of other blood-feeding parasites, including schistosomes and *Rhodnius prolixus*, but its structure and synthesis are less well understood as in *Plasmodium*. There is now considerable evidence that interference with hemozoin formation in *Plasmodium* is the mechanism of antimalarial action of 4-aminoquinolines and artemisinins.

Hepar

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek term for the liver.

Heneguya

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of ► [Myxozoa](#) in fish (Fig. 1).

Hepatic Stellate Cells

These cells are activated and multiplied in the wall of liver blood vessels in case of chronic diseases, which may be induced by parasitic infections (e.g., due to schistosomes, *Clonorchis*, *Echinococcus*, etc.).

Heneguya, Fig. 1 Light micrographs of differently shaped spores of different species in fishes.

Hepatitis Interstitialis Parasitaria Multiplex

Syndrome due to infection with *Ascaris suum* in pigs. ▶ [Ascaris](#), ▶ [Milk Spots](#).

Hepatocystis

Genus of coccidian blood parasites, the species of which are transmitted by midges (▶ [Ceratopogonidae](#), ▶ [Culicoides](#)) mainly to monkeys (*H. kochi*, *H. simiae*) in Africa and to other hosts (including hippos). Inside liver cells giant schizonts = meronts of 4 mm are formed, while in red blood cells only gamonts occur.

Hepatomegaly

Name

Greek: *hepar* = liver, *megale* = large.
Enlarged liver due to infections with schistosomes, *Echinococcus*, *Entamoeba*, opisthorchiasis, ▶ [visceral leishmaniasis](#) (▶ [Kala Azar](#)), ▶ [Chagas' disease](#) (hepatosplenomegaly).

Hepatoxylon

Genus of trypanorhynchid tapeworms in fish (▶ [Trypanorhyncha](#)).

Hepatozoon

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *hepar* = liver, *zoon* = animal.

Classification

Genus of ▶ [Coccidia](#).

Important Species

In 2003, it was shown that within dogs two tick-transmitted *Hepatozoon* species exist (perhaps another is transmitted by fleas) (Table 1):

1. *H. canis*, which is well adapted to its host (dogs) with low graded symptoms of disease.
2. *H. americanum*, which produces severe and frequently fatal myositis, is highly virulent. It has apparently recently crossed the species barrier from a wild host to pet dogs.

Life Cycle

See Figs. 1, 2, and 3.

Hepatozoon, Table 1 Important species of the genus *Hepatozoon*

Species	Host	Hosts/habitat	Vector/habitat	Mode of infection/ transmission
<i>Hepatozoon muris</i> (syn. <i>perniciosum</i>)	2	Rats, mice/liver cells, leukocytes	Rat mites (<i>Echinolaelaps</i> sp.)/hemocoel	Blood meal of vector
<i>H. erhardovae</i>	2	Bank voles (<i>Clethrionomys</i> sp.)/lung, leukocytes	Rat fleas/hemocoel	Blood meal of vector
<i>H. canis</i>	2	Dogs/liver cells, spleen leukocytes	Ticks (<i>Rhipicephalus sanguineus</i> , <i>Ixodes</i> spp.)	Blood meal of vector
<i>H. aegypti</i>	2	Snakes (<i>Spalerosophis diadema</i>)/lung, erythrocytes	Mosquitoes (<i>Culex pipiens</i>)/body cavity	Blood meal of vector

Hepatozoon, Fig. 1 Life cycle of *Hepatozoon aegypti* inside snakes (*Spalerosophis diadema*; Colubridae) and ► **mosquitoes** (*Culex pipiens*). 1, 2 Sporozoites are injected during bite of the female mosquito and enter the lung capillaries of the snake. 3–5 After penetration into endothelial cells (3), they grow to be schizonts (4), which form merozoites (5). 6 The free merozoites may enter other endothelial cells, where they repeat ► **schizont** formation (3) or penetrate into erythrocytes and become gamonts of

different sex. 7, 8 After sucking by a mosquito, the gamonts are set free (7), migrate into the hemocoel, and penetrate into host cells, where they associate in pairs within a ► **parasitophorous vacuole** (8). 9 On day 2 after infection, differentiation to micro- and macrogamonts occurs. 10 Nucleus of microgamonts divides. 11 Formation of the nonflagellated ► **microgametes** on day 3 after infection. 12, 13 Fertilization on day 4 and growth of the young ► **oocyst** during the following days. 14 Formation of

Hepatozoon, Fig. 2 LM of a stage in a white blood cell of a Giemsa-stained smear

Disease

Infections with *H. canis* are (often) symptomless but may be potentially fatal due to lethargy, cachexia, and anemia. Often 1–5 % of the neutrophils are infected and more than 50,000 gamonts may be found per microliter of the blood of dogs. The infections emerging today due to *H. americanum*, however, lead to a debilitating and often fatal disease, starting with fever, muscle atrophy, and fatal myositis (due to heart infections). The vector of *H. americanum* is *Amblyomma maculatum* (so-called Gulf Coast tick). Natural hepatozoonosis similar or identical to *H. canis* was reported also in coyotes (*Canis latrans*) as well as that due to *H. americanum*.

H

Hepatozoon clamatae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This apicomplexan species infects the erythrocytes of green frogs (e.g., *Rana clamitans*) and is transmitted by *Culex territans* mosquitoes, which are widespread through North America and Europe feeding preferably on frogs, but also on snakes.

Further Reading

Then the ► **sporoblast** forms a smooth wall and thus becomes a ► **sporocyst**. 16 These sporocysts become disrupted, leading to distribution of sporozoites inside the vector. The main method of infection

is the bite, but in experiments, oral infection of snakes was also possible. DM developing ► **merozoite**, E erythrocyte, G gamonts (of different sex), HC host cell, MA macrogamont, MI microgamont, MG microgamete, N nucleus, NH nucleus of the host cell, PV parasitophorous vacuole, SB sporoblast, SPC sporocyst

Hepatozoon sipedon

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This apicomplexan species uses as intermediate hosts snakes (e.g., common garter snakes = *Thamnophis sirtalis*, Northern water snake = *Nerodia sipedon*), where it parasitizes inside erythrocytes. Final hosts are mosquitoes (mainly *Culex pipiens*), which are the most widespread mosquito species in the world feeding mainly on birds but also on snakes. *H. sipedon*, however, requires additionally a ranid frog (e.g., *Rana pipiens*) as an additional vertebrate host. These frogs serve as an intermediate host, since they eat mosquitoes before finally they themselves are ingested by snakes. Inside the mosquitoes, it takes about 30 days until transmittable stages are finished.

Hermaphrodite

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek, *Hermes* = male god (the messenger of god father Zeus); *Aphrodite* = goddess of love

This term describes animals and humans that possess both types of sexual organs (e.g., most digenetic trematodes, most adult tapeworms).

Hermaphroditism

Name

Greek: *hermaphroditos* = son of the god Hermes and the goddess Aphrodite (= a bisexual stage).

The parasitic stages may be monoecious (hermaphroditic) having male and female gonads in a single individual. Male and female gonads usually mature at different times, but are visibly present in the same individual. Most common is ► [protandry](#) (► [Androgyny](#)), with maturation of the male gonads first; the inverse, ► [protogyny](#)

(► [Gynandry](#)), is relatively uncommon (e.g., in a few ► [tapeworms](#)). In addition, a peculiar type of protandry is found in some ► [nematodes](#) and arthropods, where individuals develop female gonads only after the complete disappearance of the male ones, thus leading to a misleading ► [dioecious](#) appearance. Hermaphroditism (with cross-fertilization) is the rule in some groups (platyhelminths, with exceptions such as schistosomes), whereas nematodes, acanthocephalans, pentastomids, and arthropods are dioecious (again, with some exceptions or modifications).

Hermetia illucens

This co-called Black soldier fly (family Stratiomyidae) is often found in masses around poultry and swine houses. The adults are 2 cm long, with black legs and white-yellow tarsi. The antennae are long, project directly forward from the head, and the last segment (3rd) is tapered with no arista. The larvae reach a size of 2 cm, grow in manure of livestock and poultry. They induce the manure to become more liquified and thus suitable for the housefly larvae.

Heronimus chelydrae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This 15 mm-long digenetic fluke is found as an adult in the lungs of turtles.

Herpobdella

Genus of leeches that may transmit trematodes of fish.

Heterobilharzia americana

Schistosoma spp. in dogs, which induces bloody diarrhoea, anorexia, loss of weight, and hypoalbuminaemia.

Heterogony

Name

Greek: *heteros* = different, *gone* = offspring.

Follow-up of generations that reproduce by

- [parthenogenesis](#) or bisexual intercourse, e.g.,
- [Strongyloides stercoralis](#).

Heterolobosea

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Phylum of amebae including the class Schizopyrenidea (e.g., ► [Naegleria fowleri](#)).

Heterophyes heterophyes

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *heteros* = different; *phyes* = shape, form.

Geographic Distribution/Epidemiology

This trematode worm occurs in several regions of East Africa, Egypt, and South Europe. About

Heterophyes heterophyes, Fig. 1 Life cycle of *Heterophyes heterophyes*. This fluke, which reaches a size of about 2×0.4 mm and is characterized by a large muscular bulbus (close to the ventral sucker) around the genital openings, lives in the small intestine and cecum of fish-eating mammals including man (A, D). It has snails (B, e.g., *Pirenella conica*) as first and various brackish or freshwater fish (C, e.g., *Oreochromis* spp., *Tilapia* spp., *Mugil* spp.) as second intermediate hosts. 1 Adult worm, ventral side. 2 The small-sized (27×16 µm) eggs, which are operculated and contain a ► *miracidium* larva, are set free within feces of the final host (A). They become ingested by snails (B) which are found in the Eastern Mediterranean Sea and Red Sea and Gulf and may reach

a length of up to 3 cm. 3 After several reproduction phases (like in *Clonorchis*) including one ► *sporocyst* generation and often 2 ► *redia* stages, tailed ► *cercariae* are released from the snail and penetrate into the skin of fish (C). The cercariae reach a total size of 185×90 µm. 4 Only the head of the cercaria penetrates into the host and becomes encysted as the so-called metacercaria (size, 0.8 mm in diameter) under the scales or in the muscles of fish. Humans (D) become infected by eating raw, pickled, or insufficiently cooked contaminated fish. The metacercariae excyst in the intestinal tract, become attached to its wall, and reach maturity within 1–2 weeks (G = gonotyl, sexual sucker; H = head of cercaria; M = metacercaria; MI = miracidium; OP = ► operculum; T = tail of cercaria)

Heterophyes

***heterophyes*, Fig. 2** Light micrograph of an adult *H. heterophyes* worm (stained ventral side)

***Heterophyes heterophyes*, Fig. 3** Scanning electron micrograph of an adult *H. heterophyes* worm (ventral side)

***Heterophyes heterophyes*, Fig. 4** Light micrograph of an adult *H. heterophyes* worm (BS = ventral sucker; DO = tegumental thorns; G = gonotyl; HO = testes; MS = oral sucker; PH = pharynx; UE = uterus with eggs)

30 millions of humans are infected besides dogs, cats, and some other fish-eating mammals.

Morphology/Life Cycle

This hermaphroditic worm with a thorny surface reaches a size of 2×0.4 mm and parasitizes inside

the small intestine and also in the ceca (Figs. 1 and 2). Characteristic is a ventrally located bulbous, which surrounds the two genital openings (σ ♀) being situated below the ventral sucker. The yellowish-brown eggs are operculated (Fig. 3), measure $25\text{--}30\ \mu\text{m} \times 15\text{--}17\ \mu\text{m}$, and are excreted within the feces of humans and/or animals. The life cycle is similar to that of ► *Clonorchis*

***Heterophyes heterophyes*, Fig. 5** Light micrograph of the eggs (containing a miracidium) of *H. heterophyes*

sinensis; however, a second intermediate host, mainly fish of brackish water, is used. Infections of final hosts occur due to oral uptake of raw meat of infected fish. In some regions of Egypt and South Europe, up to 25 % of cats and dogs are infected (Figs. 4 and 5).

Symptoms of Disease (Heterophyiasis)

Infection with masses of these worms may lead to severe diarrheas within a short time after infection. In cases of penetration of the worms into the intestinal wall, they may become driven via the bloodstream into the lung, heart, brain, etc., where they induce often big damages that may lead to death of these persons or animals.

Diagnosis

Microscopical determination of the brownish eggs (Fig. 5) after use of concentration methods (S.A.F.C. or ► [M.I.F.C.](#) or ► [flotation](#)).

Infection

Oral uptake of metacercariae in raw fish meat (e.g., members of the family Mugilidae).

Prophylaxis

Avoid to eat raw or undercooked meat of fish or to feed pet animals with this type of food.

Incubation Period

One to three weeks.

Prepatent period

One to three weeks.

Patency

Two to six months.

Therapy

Praziquantel: see *Clonorchis*.

Heterophyiasis, Man

Disease due to infections with *Heterophyes* species via oral uptake of uncooked infected fish.

Heterophyiasis, Man, Fig. 1 LM of *Heterophyes heterophyes* eggs from feces

Main clinical symptoms: Diarrhoea, abdominal pain.

Incubation period: 1–3 weeks.

Prepatent period: 1–2 weeks.

Patent period: 2–6 months.

Diagnosis: Microscopic determination of eggs in faecal samples (Fig. 1, 603).

Prophylaxis: Avoid eating raw fish.

Therapy: Treatment with praziquantel, see Trematodocidal Drugs.

Heteroptera

From Greek: *heteros* = different, *pteron* = wing.
► [Bugs](#).

Heteroxenous Development

Name

Greek: *heteros* = the other, *xenos* = foreigner, guest.

This term describes cycles with involvement of different hosts (e.g., Schistosomes).
► [Dixenous Development](#).

Hexacanth

The larvae of the ► [Eucestoda](#) have 6 hooks (3 pairs) and are thus described as hexacanth whereas the larvae of ► [Cestodaria](#) form 10 larval hooks (► [Decacanth](#)).

Hexachlorcyclohexan

Lindan is the χ -isomer of this compound.

Hexaflumuron

Growth regulator in insect larvae (= acts as insecticide and hinders the molt of larvae
► [Diflubenzuron](#) = Dimilin), ► [Methoprene](#).

Hexamita

Name

Greek: *hex* = six, *mitos* = filament.

Morphology

The specimens of *Hexamita salmonis* and *S. symphysodonis* parasitize in the fish intestine reach a size of about 8–12 μm in length, possess

Hexamita, Fig. 1 LM of *Hexamita* – stages from fish intestine

Hexamita, Fig. 2 SEM a *Hexamita*-stage

2 nuclei and in total 6 flagella, of which 4 become free at the anterior pole, 2 at the posterior (Figs. 1–3). Reproduction occurs by binary fission and transmission by cysts that are excreted with the feces (Figs. 2 and 3, page 604).

Symptoms of Disease

Apathy, loss of weight, white feces, death (also hollow – sickness in discus – fish).

Hexamita, Fig. 3 Diagrammatic representation of a *Hexamita*-stage

Therapy

Flagellol™ (5-nitroimidazoles). Diplomonadida.

Hexapoda

Animals with 6 ft (Insecta), from Greek: *hexa* = six, *podos* = feet.

Trematode species; mainly parasitizes as adult worm in seagulls; however, humans may become infected, if they eat raw mussels of the genera *Mytilus* or *Mya*. The life cycle runs similar to that of *Echinostoma* species.

Hippobosca equina

Name

Greek: *hippos* = horse, *boskein* = feeding on the meadow.

General Information

This “horse louse fly” reaches a length of 8 mm (Fig. 1), has yellow-red legs and reddish wings, while the thorax is black with yellow stripes. The

female places 7–10 larvae onto the soil, where they pupate within 4–6 hours. Mostly after 4 weeks (range 3–20) the adults hatch.

Symptoms

The horses are restless due to the rapid movements of the adult flies within the hair and due to their painful bites. Humans are also attacked; the pain is intensive like that of bee bites.

Hippoboscidae, Louse Flies/Keds

Reiner Pospischil
PMP-Biosolutions, Bergheim-Fliesteden,
Germany

Introduction

The louse flies belong to the order Diptera (subsection Brachycera). Various authors put them in the section Pupipara together with the Nycteribiidae (bat flies) and Streblidae, which all are permanent, obligate ectoparasites which suck blood from mammals and birds (Haupt and Haupt 1998; Hutson 1984; Schumann 2000). Both males and females stay on the host and mating occurs on the host. The females are larviparous and nurture single larvae internally within 3–8 days. The pupation takes place directly after the mature larvae are released by the females (Hutson 1984). The Hippoboscidae are closely related to the Glossinidae.

Hippoboscidae: Host Specificity

More than 200 species of louse flies are known until now. 75 % are associated to birds, and 25 % live on mammals mostly on even-toed ungulates (Artiodactyla). The species which life on birds are commonly called flat flies or louse flies. The species which are found on mammals are known as keds flies. Most species are monoxenous or oligoxenous. Only a few species were found to be polyxenous (e.g., *Ornithomya avicularia* and *Ornithomya fringillina*). European Hippoboscidae which live on mammals and their host spectra are presented in Table 1 and those which are associated to birds in Table 2, respectively.

Adaptations to the Parasitic Life

The species of the family Hippoboscidae are well characterized by their dorsoventrally flattened

body and leathery cuticle, which is covered with bristles. The claws of the tarsae are strong and curved. They are a requisite for louse flies to have

Hippoboscidae, Louse Flies/Keds, Table 2 Hippoboscidae which are associated with birds (Büttiker 1994; Corbet 1956; Hill 1962; Kasperek and Walter 1986; Schmidt 2001)

Scientific name	Host range

a firm grip on their host, even if they move fast through the fur.

Louse flies can survive only a short time (average 55 h) without food. Species which are associated with birds and release their larvae in the birds' nest provide the new generation directly with the blood source. The pupae hibernate after the birds have left the nest in autumn and synchronize hatching of the adult flies with the return of their hosts in spring (e.g., *Steneptryx hirundinis*, *Pseudolynchia canariensis*, and *Crataerina pallida*). Others which search a host actively by flying should be successful within 2–3 days (e.g., *Lipoptena* and *Hippobosca*). However, on the primary hosts, also pupae of these Hippoboscidae species may be found in the fur Trilar and Krčmar (2005). The adults of *Melophagus* hatch directly on their host, because pupation always takes place in the fur.

The wings can be partially reduced or absent depending on the species. Species which actively seek a new host by flight (e.g., *Lipoptena cervi* and *Hippobosca equina*) have fully developed wings and are fast flyers. They drop their wings once they have found a suitable host. In contrast, the representative of the parasitic species of birds *Ornithomya* and *Pseudolynchia* keep their wings for life. Louse flies which stay in the nest of their host (e.g., *Steneptryx hirundinis* and *Crataerina pallida*) have sickle-shaped, truncated wings which are unsuitable for flying. *Melophagus ovinus* and *M. rupicaprinus* do not even have wing pads and stay their whole lives on the same host individual.

Transmission of Diseases

There is some evidence that Hippoboscidae can serve as vectors of disease agents to birds and

mammals, but studies on the function of Hippoboscidae as vectors are rare. A survey of the few data on the transmission of pathogens by louse flies is given by Hutson (1984). Since they feed on the blood of their hosts, louse flies can transmit pathogens such as trypanosomes and the causative agent of avian malaria (Büttiker 1994).

Pseudolynchia canariensis is commonly found on pigeons and doves and can serve as vector of pigeon malaria. Halos et al. (2004) have shown that *Hippobosca equina*, *Lipoptena cervi*, and *Melophagus ovinus* are the most likely candidates to transmit *Bartonella* spp. to ruminants.

Short Description of Common Louse Fly Species

Hippobosca equina is the largest European louse fly with a body length of 6.5–8 mm. The species parasitizes horses, cattle, and donkeys. The fully grown larvae fall to the ground after they were released by the female and pupate. The recently hatched adults are very fast and skilful flyers, and their flight behavior resembles to horseflies (Tabanidae) and tsetse flies (Glossinidae). While searching for a suitable host, the flies often attack people, but leave them generally immediately after landing. But it sometimes happens that the flies remain for some time on people and even suck blood.

Lipoptena cervi is widespread in the Palaearctic region and common. Primary hosts are deer, but also wild boars, badgers, and foxes. People are also often attacked by young adults of *L. cervi*, where the animals hide immediately after landing in the hair and clothes and can so easily enter homes, where they stay for several days with

humans, suck blood, and even throw off the wings.

Lipoptena fortisetosa is much rarer and smaller than *Lipoptena cervi* and its distribution is unclear (Büttiker 1994). The species seems to be more prevalent in the eastern parts of Europe because of the (few) records. The newly hatched adults have a similar behavior as *L. cervi* and also attack people during searching for a host. Blood feeding on people was also observed.

Melophagus ovinus was common on domestic sheep worldwide in the past. Now it has become quite seldom. The reddish-brown and wingless adults stay their whole lives on their host, and change of the host is only possible when the flock stands close together.

Melophagus rupicaprinus occurs monoxenous on chamois in the Alpine regions. Reports from other hosts are based on confusion with *Melophagus ovinus*.

The genus *Ornithomya* comprises five Central European species that live on birds. The species are excellent flyers and do not throw off their wings after landing on a suitable host. *Ornithomya avicularia* is the most common species.

Pseudolynchia canariensis is mainly associated with pigeons and doves. It flies well and does not throw off the wings. The origin of the species is the tropics and subtropics worldwide, and it is seldom found in Central Europe. The species hibernates as a pupa in the nesting sites of the pigeons. Hatching of the adults is synchronized with the arrival of the pigeons in the nest the following spring.

Stenepteryx hirundinis parasites on house martins and is synchronized with the seasonal rhythm of the host. The species has sickle-shaped wings and cannot fly.

Crataerina pallida is adopted to swifts and its biology is similar to *S. hirundinis*. But it is larger and the fully engorged adults reach a body length of 10 mm. It is occasionally reported that

Crataerina pallida penetrates the inside of the building after the departure of the hosts and the attack people.

H

Hirnwurm

German term for metacercariae of *Dicrocoelium* inside the brain of the second intermediate host (ant). ► [Behavior](#).

Classification

Species of the leeches, which belong as Hirudinea to the order Clitellata among the worm phylum ► [Annelida](#) (Latin: *annulus* = ring).

Hirudo medicinalis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *hirudo* = leech; *medicinalis* = used in treatment as “medicine.”

Morphology and Life Cycle

Hirudo medicinalis (European medicinal leech) belongs as its relatives *Hirudo verbana* (Hungarian leech: syn. *H. officinalis*), *H. troctina*, *H. orientalis* (Asia), *Hirudinaria manillensis* (Mexican medical leech) or *Macrobdella decora* (North American medical leech), etc. to the order Gnathostomulida (Fig. 1).
Hirudo medicinalis (Fig. 2) may reach a length (when stretched) of up to 20 cm and appears greenish brown being somewhat darker at its

Hirudo medicinalis, Fig. 1 Phylogenetic relationship of medical leech species from combined nuclear and mitochondrial DNA sequences using parsimony (according to Utevski and Trontelj 2005)

Hirudo medicinalis, Fig. 3 Light micrograph of the anterior sucker showing inside the three jaws

Hirudo medicinalis, Fig. 2 Macroscopic photo of the dorsal side of a *H. verbana* leech

upper side, where in addition a thin reddish stripe is visible. As other leeches, *H. medicinalis* possesses an anterior and a posterior sucker (Figs. 3, 4). While the posterior one is mainly used for leverage (i.e., fast holding), the anterior serves for attachment and moving (Fig. 5) and

blood uptake from hosts. This is done by help of three jaws, which work as little saws due to their tiny, but very sharp teeth to incise the host's skin. The incision place looks afterward like an inverted Y. During biting the leeches inject via fine channels of their teeth (Fig. 6) hirudin, which prohibits blood coagulation, so that up to 15 ml blood can be taken up within a few minutes. This amount of blood, however, may cover the need of the leech for more than 1 year. The uptake of blood is well organized, since the leech releases via a pore the fluid components of the blood and stores only the blood cells. Thereby the leech is able to store many more of the energy-rich blood cells. After mating the hermaphroditic leeches lay clutches of 50 eggs inside of so-called cocoons close to water into which the young leeches enter having hatched from their egg. Besides hirudin the leeches also inject anesthetic compounds, apyrase, collagenases, vasodilatory elements, and proteinase inhibitors. Therefore, bites of leeches are not painful.

Leeches had been used for man more than 2,000 years for medical purposes. But their potential to transmit agents of severe diseases had been discovered only during the last 30 years. This potential vectorship is not astonishing, since the intestine stores blood as it was sucked in (e.g., with or without agents of the blood donor). During blood sucking, there are phases of regurgitation or vomiting of ingested blood of the previous into the new host, too. In experiments it was

***Hirudo medicinalis*, Fig. 4** Diagrammatic representations of *Hirudo medicinalis*. (a) Ventral aspect; the outer annulation does not correspond to the inner segments (1–32). (b) Inner structure. After copulation and transfer of so-called double spermatophores, fertilized eggs are packed together into slime (► **cocoon**) deriving from the ► **clitellum** and are deposited on plants. After a period (depending on the temperature of the water), the young worms hatch from the eggs and reach maturity within 5–6

months (A = anus; B = ventral nerve cord; BS = last intestinal cecum; C = clitellum; D = intestinal ceca; DG = dorsal blood vein; E = nephropores = openings of the 17 pairs of ► **metanephridia**; ED = rectum; G = genital porous; H = testis; HD = hind gut; HS = posterior ► **sucker**; NE = nephridium; O = ovary; P = penis; PH = pharynx; S = sensory papillae; SD = salivary glands; V = vagina; VS = apical sucker)

connective tissue; BK = blood capillary; ES = terminal portion of the unicellular salivary glands; EZ = epithelium cell; K = jaw; KU = cuticle; N = nucleus; PH = pharynx; S = drop of saliva; SD = salivary gland with secret granules; ZK = opening channel of the unicellular salivary glands)

shown by Nehili et al (1994) that practically all important human blood parasites could be transmitted via this pathway. Therefore it makes sense that free-living leeches are not more used for medicinal purposes. This is not more needed today, since the hirudin is now produced by molecular biological methods.

Histomonas meleagridis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

1. **Name:** Greek: *histos* = tissue; *monas* = organism; *meleagris* = guinea fowl (the sisters of the Greek warrior Meleagros (= comrade of Odysseus in the Trojan war) were transformed into chicken while mourning due to the death of her brother).
2. **Geographic distributions/epidemiology:** Worldwide. In extreme large farms, epidemics

***Histomonas meleagridis*,**

Fig. 1 Light micrographs of stages of *H. meleagridis* with one or no flagellum

H

***Histomonas meleagridis*,**

Fig. 2 Diagrammatic representation of stages of *H. meleagridis* with or without a flagellum

are common and all animals have to be killed in prevention on further spreading.

3. **Morphology/life cycle:** The spherical trophozoites occur in the intestine (coeca) of numerous birds but especially in turkeys. Another species (*H. isolonche*) is described in pheasants. They measure 5–30 μm in diameter and show often 1 single flagellum besides others without any flagellum (Figs. 1 and 2). Occasionally stages are seen with 2–4 flagella which apparently occur due to interrupted sequences of divisions. The reason why some 8–15 μm -sized stages leave the intestine and enter the liver (Fig. 4) is not yet understood. According to recent findings, cyst stages occur (Fig. 2). These stages were apparently excreted within the feces, from where they were ingested by other birds and start new infections. The history that intestinal stages of *H. meleagridis*

enter eggs of the nematode *Heterakis gallinae* is apparently wrong, since many infections with *H. meleagridis* were diagnosed without any presence of this worm.

4. **Symptoms of disease (histomoniasis, blackhead disease, necrotic enteritis, enterohepatic syndrome):** In acute cases, the following symptoms were seen: yellowish diarrheas, absolute weakness, necrotic hepatitis, blue-black-appearing skin of head (= name giving), anemia (15–100 %); death.
5. **Diagnosis:** Microscopical demonstration of the trophozoites and cysts in fresh diarrheal feces.
6. **Infection:** Oral uptake of infectious stages in fecally contaminated food or in water.
7. **Prophylaxis:** Separation of birds younger than 4 months from others, since the disease is dominant in young birds.

***Histomonas meleagridis*, Fig. 3** Cyst stages of *H. meleagridis* in feces of a turkey obtained after experimental infections

***Histomonas meleagridis*, Fig. 4** Macrophoto of the liver of a *H. meleagridis*-infected turkey. Note the typical white granulomas

8. **Incubation period:** About 6–9 days.
9. **Prepatent period:** 2–5 days: then already infected mucous layers can be seen.
10. **Patency:** Older animals may be infected during their whole life-span.
11. **Therapy:** In many countries no medicament is available. Thus, it is needed to inform officially the local governmental veterinary authorities.

Historical Landmarks

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Parasites do not accept borderlines. Thus, parasitology has been an international and

interdisciplinary science from its beginnings in early human cultures. Philosophers, theologians, natural scientists, pharmacists, physicians, and veterinarians gave birth to deep insights into the world of parasites. Some of the highlights, the selection of which is, of course, an expression of personal taste, are listed below (Table 1, pp. 1361–613).

Historical Landmarks, Table 1 Historical landmarks (not complete)

1500 BC	The Egyptian Papyrus Ebers reported on human worms and schistosomiasis
500 BC	The Greek poet Herodot reported that the Egyptians use fine nets against mosquitoes
430 BC	Hippocrates (460–399 BC) described <i>Ascaris</i> , <i>Oxyuris</i> , adult <i>Taenia</i> , and malaria
342 BC	The great Greek natural scientist Aristoteles (384–322 BC) established a first classification system for animals (<i>Historia animalium</i>)
62 AD	In his <i>Historia naturalis</i> , the Roman Lucius Columella (40–88 AD) reported on parasitic animal diseases. Plinius Secundus (23–79 AD) also wrote on this subject
158 AD	The Roman physician Claudius Galen (129–199 AD) propagated the knowledge of Hippocrates
480 AD	The Roman Vegetius Renatus (450–510 AD) published his <i>Ars veterinaria</i> with detailed descriptions of intestinal worms
1000	Avicenna (Abu Ali El-Hosein Abdallah Ibn Sina, 980–1037). This Persian theologian and physician reported in his book <i>Liber canonis totius medicinae</i> on malaria and on many worms, especially on <i>Dracunculus</i> , which today in French is still called <i>fil d’ Avicenne</i>
1150	Hildegard of Bingen (1098–1179). This German nun published methods of treating worms in her <i>De causis et curis morborum</i>
1220	Albertus Magnus (1193–1280). This German theologian and physician reported in his 26-volume opus <i>De animalibus</i> on Aristoteles’ insights
1498	Savonarola (1452–1498). In his <i>Tractatus de vermibus</i> , this Italian scientist described the occurrence and treatment (by mercury) of worm-infected humans
1520	The German physician P.A.T. Bombastus von Hohenheim, called Paracelsus (1496–1541), introduced inorganic salts (e.g., zinc salts) as anthelmintics.
1552	The Belgian physician Cornelius Gemma (1534–1579) published the first picture of a human tapeworm
1583	Discovery of quinine for malaria treatment by an unknown Peruvian (Indian) and the Augustinian monk Antonio de la Calancha
1674–1681	The Dutch optician and autodidact Antonie van Leeuwenhoek (1632–1723) described oocysts of the later established genus <i>Eimeria</i> and several <i>Giardia</i> stages taken from its own feces
1684–1698	The Italian physician and philosopher Francesco Redi (1626–1697) described in his book <i>Osservazioni intorno agli animali viventi</i> about 108 different worms and published (in 1698) a detailed study on <i>Fasciola hepatica</i> . Due to his leadership, he is considered the father of parasitology – the name rediae for special trematode developmental stages honors this
1699	The Dutchman Nicolaas Hartsoecker (1656–1725) and the Frenchman J. Andry (1658–1742) proposed that helminth infections derive from oral intake of excreted worm eggs
1717	The Italian Lancisco postulated that malaria is caused by bites from mosquitoes
1739–1778	The Swedish physician Carl von Linné (1707–1778) created within the different editions of his book <i>Systema naturae</i> a comprehensive system of classification of animals and plants
1756	The English physician Alexander Russell (1715–1768) discovered in Aleppo the skin leishmaniasis
1766	The German physician and natural scientist Peter Simon Pallas (1741–1811) was the first to begin the experimental transmission of parasites to animals
1782	The German theologian J.A.E. Goeze (1731–1793) initiated the taxonomy of helminths

(continued)

Historical Landmarks, Table 1 (continued)

1790	The Danish pharmacist and veterinarian P.C. Abildgaard (1740–1801) experimentally transmitted <i>Diphyllbothrium</i> larvae to chicken
1801	The German physician and natural scientist Karl Asmund Rudolphi (1771–1832) published his <i>Entozoorum, sive vermium intestinalium: historia naturalis with a taxonomy of all available parasites</i>
1801	The French natural scientist Jean Baptiste Lamarck (1744–1829) presented the first general theory of the evolution within his <i>Philosophie Zoologique</i>
1820	The French scientists Pierre Joseph Pelletier and Joseph Lavendou isolated quinine from plants
1835	The English medical student J. Paget (1814–1899) and his teacher R. Owen described trichinas in human muscles. Since the name originally given, <i>Trichina</i> , was prefixed for an insect, the worm name was changed in <i>Trichinella</i> by Railliet (1895)
1838	The German scientists M. Schleiden and Theodor Schwann (1810–1882) formulated the cell theory , which became the dead end for the former <i>de novo</i> creation theory
1841	The Swiss scientist G.G. Valentin described the first trypanosomes in the blood of a salmonid fish
1848	The American Josiah Nott postulated again that mosquitoes were vectors of malaria and yellow fever
1849	The Swiss G. Gross discovered <i>Entamoeba gingivalis</i> as the first parasitic amoeba
1853	The German C.T.E. von Siebold (1804–1885) showed the life cycle of <i>Echinococcus granulosus</i>
1859	The Germans Rudolph Virchow (1821–1902) and Rudolph Leuckart (1822–1898) independently found the life cycle of <i>Trichinella spiralis</i>
1859	The English philosopher, theologian, and natural scientist Charles Darwin (1809–1882) published his <i>The Origin of Species</i> – another landmark of the evolution theory
1865	The Bohemian monk Gregor Mendel (1822–1884) formulated the basic laws of genetics
1869	The German physician Otto Wucherer (1820–1873) discovered in Brazil microfilariae and schistosome eggs in human urine
1875	The German physician F.A. Lösch described at the court in St. Petersburg (Russia) for the first time stages of <i>Entamoeba histolytica</i>
1878	The Scottish scientist Sir Patrick Manson (1844–1922) working in China showed that <i>Wuchereria bancrofti</i> is transmitted by mosquitoes (<i>Culex</i> sp.)
1880	The Frenchman Charles L.A. Laveran (1845–1922) showed malaria stages within erythrocytes
1882	The Russian scientist Ilya Metchnikoff (1845–1916), working in Italy, was the first to describe the phenomenon of phagocytosis and to develop the concept of cellular immunity (Nobel Prize 1908)
1885	A.L.J. Railliet (1852–1930). This French zoologist described a large range of protozoans and helminthes
1888	The French physiologist Charles Richet (1855–1935) formulated the basic concept of humoral immunity (Nobel Prize 1919)
1890	The German veterinarian Robert von Ostertag (1864–1940) described a large variety of parasitic nematodes in animals
1893	The Americans Theobald Smith and F.L. Kilbourne identified the transmission of <i>Babesia bigemina</i> by ticks (<i>Boophilus annulatus</i>)
1895	The English military physician David Bruce (1855–1932) showed that the tsetse fly is the vector of animal trypanosomes
1897	In India the English Army doctor Sir Ronald Ross (1857–1932) proved that avian malaria was transmitted by <i>Anopheles</i> mosquitoes (Nobel Prize in 1902). In the same year the Italians Bignami, Bastianelli, and Grassi did the same for human malaria
1898	The German physician and discoverer of the agent of tuberculosis (<i>Mycobacterium tuberculosis</i>) Robert Koch (1843–1910) described <i>Theileria parva</i> , the agent of East Coast fever (Nobel Prize 1905)
1898	The Frenchman P.L. Simond succeeded in demonstrating the transmission of plague by rat fleas
1900	In Cuba an American group working with Walter Reed demonstrated the transmission of yellow fever by <i>Aedes aegypti</i>
1903	The English scientists W. B. Leishman and C. Donovan independently described <i>Leishmania donovani</i> , the agent of kala-azar disease
1904	In Cairo the German helminthologist Arthur Looss (1861–1923) discovered the transmission of the hookworm

(continued)

Historical Landmarks, Table 1 (continued)

1906	The American physician Howard T. Ricketts (1878–1910) recorded the tick <i>Dermacentor andersoni</i> as being a vector of the agents of the Rocky Mountain spotted fever
1906	The German zoologist and discoverer of the agent of syphilis Fritz Schaudium (1871–1906) described <i>Entamoeba histolytica</i> as a human parasite
1907	The American E.E. Tyzzer described stages of the genus <i>Cryptosporidium</i>
1907	The German chemist Paul Ehrlich (1854–1925) – the father of chemotherapy – proposed the drug trypan red against trypanosomiasis (Nobel Prize 1908)
1908	In North Africa the French military doctors Charles Nicolle (1866–1936) and L.H. Manceaux described <i>Toxoplasma gondii</i> in a rodent
1909	The Brazilian Carlos Chagas (1879–1934) discovered the life cycle of <i>Trypanosoma cruzi</i> and described <i>Pneumocystis carinii</i>
1909	Teams working with the Frenchman Charles Nicolle (1866–1936) (Tunis) and the American H.T. Ricketts (Mexico) proved that the louse <i>Pediculus humanus corporis</i> is a vector of the typhus-causing rickettsia
1910	The Italian Carini discovers <i>Pneumocystis carinii</i> in rats
1914	The Japanese scientists M. Miyairi and M. Suzuki worked out the life cycle of <i>Schistosoma japonicum</i> .
1916–1920	Development of suramin (B205) against trypanosomiasis (Bayer Co., Germany)
1917	The Austrian psychiatrist Julius Wagner Ritter von Jauregg (1857–1940) tested a live vaccination using <i>Plasmodium vivax</i> stages (Nobel Prize 1927)
1925	The English natural scientist D. Keilin elucidated the electron cascade (cytochrome) system while using parasitic insects and worms as models
1934	Discovery of chloroquine as a malariacidal drug at Bayer Co. (Wuppertal, Germany)
1938	The German scientists Helmut and Ernst Ruska developed the transmission electron microscope at Siemens Co. (Berlin) (Nobel Prize 1985)
1939	Sulfonamides were introduced as anticoccidial drugs, and the Nobel Prize was awarded to their discoverer Gerhard Domagk (1895–1964) (Bayer Co., Leverkusen, Germany)
1944	Erich Reichenow and N. Mudrow (Leverkusen, Germany) demonstrated the liver stages of avian malaria
1950	In the USA C. Bueding demonstrated the carbohydrate metabolism in <i>Schistosoma mansoni</i>
1953	The Americans J.D. Watson and F.H.C. Crick described the structure of DNA
1955	DDT, which had been developed in 1939 by the Swiss Paul Müller , was introduced as an insecticide
1956	The English scientists P.C.C. Garnham and S. Short demonstrated the liver stages of <i>Plasmodium</i> within humans
1959	The English natural scientist J.D. Smyth and J.A. Clegg elucidated the eggshell formation in flatworms
1960	Erich Scholtzseck (Bonn, Germany) and Datus Hammond (Logan, Utah) started systematical electron microscopic studies on Coccidia
1961	The American L.S. Diamond cultured <i>Entamoeba histolytica</i> axenically
1961	First reports on chloroquine resistance in Asia and Africa
1963	The Americans F.M. Fischer and R.M. Sanborn demonstrated that the microsporidian <i>Nosema</i> produces juvenile hormones for its insect host
1963	The Americans C.P. Read , A.H. Rothman , and J.E. Simmons demonstrated the basics of the membrane transport in cestodes
1964	The American R. Damian proved molecular mimicry in schistosomes
1965	The Australian W.P. Rogers discovered the role of enzymes in the molting of nematodes
1966	Introduction of benzimidazoles as broad spectrum anthelmintics
1969	The American Jack Frenkel (Kansas) and the Indian J.P. Dubey together described the cat as final host of <i>Toxoplasma gondii</i> . Work and Hutchinson (Scotland) and Overdulve (Holland) independently achieved the same result
1972–1977	German research teams led by Micheal Rommel , Alfred Otto Heydorn , and Heinz Mehlhorn discovered and described the life cycles of several <i>Sarcocystis</i> species and related cyst-forming species
1975	Georg Köhler and J. Milstein developed the hybridoma technique for the production of monoclonal antibodies (Nobel Prize 1986)

(continued)

Historical Landmarks, Table 1 (continued)

1975	The English biologist C. Cross characterized the glycoprotein surface coat of trypanosomes
1975–1978	German research teams led by Eberhard Schein , Karl Friedhoff , and Heinz Mehlhorn discovered the complete life cycles of ten <i>Theileria</i> and <i>Babesia</i> species
1976	The Americans Trager and Jensen succeeded in establishing continuous <i>in vitro</i> cultures of <i>Plasmodium falciparum</i>
1976	The American C.H. Zierdt and the Chinese J. Tan introduced <i>Blastocystis</i> as a parasite
1978	The Scottish scientists Keith Vickerman and G.A.M. Cross demonstrated antigenic variation in the surface coat of trypanosomes
1981	Introduction of ivermectin
1981	The Swiss Burgdorfer recognized <i>Ixodes</i> ticks as vectors of <i>Borrelia</i> bacteria, the agent of Lyme disease
1982	American scientists defined the first malaria antigen-circumsporozoite antigen
1984	The threat of AIDS was growing and the importance of opportunistic parasites became recognized
1985	Application of PFGE to parasitological problems
1986	Recognition of the importance of zymodemes for the identification of strains of <i>Trypanosoma cruzi</i>
1987	Use of DNA probes in the field
1988	Application of DNA-amplification techniques in parasitology
1988	The Colombian microbiologist M.E. Patarroyo presented a synthetic vaccine against <i>Plasmodium falciparum</i>
1989	RNA editing in parasites
1989	RNA editing was found to occur in trypanosomes
1990	Possible role of transgenic mosquitoes in control measures
1990	The reasons for sequestration in <i>Plasmodium falciparum</i> were detected
1991	Cross regulation of Th1 and Th2 subsets in parasitic infections
1991	The function of nitric oxide in human malaria and other parasitic infections was detected
1992	Potential of understanding genomes of parasites and vectors
1993	Avermectins and management of arthropods of medical and veterinary importance
1993	M.E. Patarroyo reported on the first successful malaria vaccine trials in South America (failures occurred later)
1994	HIV-AIDS and leishmaniasis
1995	Trials of the SPf66 malaria vaccine in humans
1996	Combination therapy for malaria
1997	Global mapping of filariasis
1998	Climate change and vector-borne diseases
1999	Roll Back Malaria initiative
2000	<i>Wolbachia</i> in filarial worms as a target for chemotherapy
2000	<i>Plasmodium falciparum</i> genome completed
2001	Apoptosis of intracellular protozoa
2002	Genetic analysis of arthropod blood meals
2003	Transgenic mosquitoes and malaria control
2003	Human genome completed
2004	DNA microarray analysis of protozoan gene expression Application of DNA fingerprinting to forensic science Beginning of the Human Genome Project
1500 BC	The Egyptian Papyrus Ebers reported on human worms and schistosomiasis
500 BC	The Greek poet Herodot reported that the Egyptians use fine nets against mosquitoes
430 BC	Hippocrates (460–399 BC) described <i>Ascaris</i> , <i>Oxyuris</i> , adult <i>Taenia</i> , and malaria
342 BC	The great Greek natural scientist Aristoteles (384–322 BC) established a first classification system for animals (<i>Historia animalium</i>)
62 AD	In his <i>Historia naturalis</i> , the Roman Lucius Columella (40–88 AD) reported on parasitic animal diseases. Plinius Secundus (23–79 AD) also wrote on this subject

(continued)

Historical Landmarks, Table 1 (continued)

158 AD	The Roman physician Claudius Galen (129–199 AD) propagated the knowledge of Hippocrates
480 AD	The Roman Vegetius Renatus (450–510 AD) published his <i>Ars veterinaria</i> with detailed descriptions of intestinal worms
1000	Avicenna (Abu Ali El-Hosein Abdallah Ibn Sina, 980–1037). This Persian theologian and physician reported in his book <i>Liber canonis medicinae</i> on malaria and on many worms, especially on <i>Dracunculus</i> , which today in French is still called <i>fil d' Avicenne</i>
1150	Hildegard of Bingen (1098–1179). This German nun published methods of treating worms in her <i>De causis et curis morborum</i>
1220	Albertus Magnus (1193–1280). This German theologian and physician reported in his 26-volume opus <i>De animalibus</i> on Aristoteles' insights
1498	Savonarola (1452–1498). In his <i>Tractatus de vermibus</i> , this Italian scientist described the occurrence and treatment (by mercury) of worm-infected humans
1520	The German physician P.A.T. Bombastus von Hohenheim, called Paracelsus (1496–1541) introduced inorganic salts (e.g., zinc salts) as anthelmintics
1552	The Belgian physician Cornelius Gemma (1534–1579) published the first picture of a human tape-worm
1583	Discovery of quinine for malaria treatment by an unknown Peruvian (Indian) and the Augustinian monk Antonio de la Calancha
1674–1681	The Dutch optician and autodidact Antonie van Leeuwenhoek (1632–1723) described oocysts of the later established genus <i>Eimeria</i> and several <i>Giardia</i> stages taken from its own feces
1684–1698	The Italian physician and philosopher Francesco Redi (1626–1697) described in his book <i>Osservazioni intorno agli animali viventi</i> about 108 different worms and published (in 1698) a detailed study on <i>Fasciola hepatica</i> . Due to his leadership he is considered the Father of Parasitology – the name rediae for special trematode developmental stages honors this
1699	The Dutchman Nicolaas Hartsoeker (1656–1725) and the Frenchman J. Andry (1658–1742) proposed that helminth infections derive from oral intake of excreted worm eggs
1717	The Italian Lancisco postulated that malaria is caused by bites from mosquitoes
1739–1778	The Swedish physician Carl von Linné (1707–1778) created within the different editions of his book <i>Systema naturae</i> a comprehensive system of classification of animals and plants
1756	The English physician Alexander Russel (1715–1768) discovered in Aleppo the skin leishmaniasis
1766	The German physician and natural scientist Peter Simon Pallas (1741–1811) was the first to begin the experimental transmission of parasites to animals
1782	The German theologian J.A.E. Goeze (1731–1793) initiated the taxonomy of helminths
1790	The Danish pharmacist and veterinarian P.C. Abildgaard (1740–1801) experimentally transmitted <i>Diphyllbothrium</i> -larvae to chicken
1801	The German physician and natural scientist Carl Asmund Rudolphi (1771–1832) published his <i>Entozoorum, sive vermium intestinalium: historia naturalis with a taxonomy of all available parasites</i>
1801	The French natural scientist Jean Baptiste Lamarck (1744–1829) presented the first general theory of the evolution within his <i>Philosophie Zoologique</i>
1820	The French scientists Pierre Joseph Pelletier and Joseph Lavendou isolated quinine from plants
1835	The English medical student J. Paget (1814–1899) and his teacher R. Owen described trichines in human muscles. Since the name originally given, <i>Trichina</i> , was prefixed for an insect, the worm name was changed in <i>Trichinella</i> by Railliet (1895)
1838	The German scientists N. Schleiden and Theodor Schwann (1810–1882) formulated the cell theory , which became the dead end for the former <i>de-novo</i> -creation-theory
1841	The Swiss scientist G.G. Valentin described the first trypanosomes in the blood of a salmonid fish
1848	The American Josiah Nott postulated again that mosquitoes were vectors of malaria and yellow fever
1849	The Swiss G. Gross discovered <i>Entamoeba gingivalis</i> as the first parasitic amoeba
1853	The German C.T.E. von Siebold (1804–1885) showed the life cycle of <i>Echinococcus granulosus</i>
1859	The Germans Rudolph Virchow (1821–1902) and Rudolph Leuckart (1822–1898) independently found the life cycle of <i>Trichinella spiralis</i>
1859	The English philosopher, theologian and natural scientist Charles Darwin (1809–1882) published his <i>Origin of species</i> – another landmark of the evolution theory

(continued)

Historical Landmarks, Table 1 (continued)

1865	The Bohemian monk Gregor Mendel (1822–1884) formulated the basic laws of genetics
1869	The German physician Otto Wucherer (1820–1873) discovered in Brazil microfilariae and schistosome eggs in human urine
1875	The German physician F.A. Lösch described at the Court in St. Petersburg (Russia) for the first time stages of <i>Entamoeba histolytica</i>
1878	The Scottish scientist Sir Patrick Manson (1844–1922) working in China showed that <i>Wuchereria bancrofti</i> is transmitted by mosquitoes (<i>Culex</i> sp.)
1880	The Frenchman Charles L.A. Laveran (1845–1922) showed malaria stages within erythrocytes
1882	The Russian scientist Ilja Metchnikoff (1845–1916), working in Italy, was the first to describe the phenomenon of phagocytosis and to develop the concept of cellular immunity (Nobel Prize 1908)
1885	A.L.J. Railliet (1852–1930); this French zoologist described a large range of protozoans and helminthes
1888	The French physiologist Charles Richet (1855–1935) formulated the basic concept of humoral immunity (Nobel Prize 1919)
1890	The German veterinarian Robert von Ostertag (1864–1940) described a large variety of parasitic nematodes in animals
1893	The Americans Theobald Smith and F.L. Kilbourne identified the transmission of <i>Babesia bigemina</i> by ticks (<i>Boophilus annulatus</i>)
1895	The English military physician David Bruce (1855–1932) showed that the tsetse fly is the vector of animal trypanosomes
1897	In India the English Army doctor Sir Ronald Ross (1857–1932) proved that avian malaria was transmitted by <i>Anopheles</i> mosquitoes (Nobel Prize in 1902). In the same year the Italians Bignami, Bastianelli and Grassi did the same for human malaria
1898	The German physician and discoverer of the agent of tuberculosis (<i>Mycobacterium tuberculosis</i>) Robert Koch (1843–1910) described <i>Theileria parva</i> , the agent of East Coast fever (Nobel Prize 1902)
1898	The Frenchman P.L. Simond succeeded in demonstrating the transmission of plague by rat fleas
1900	In Cuba an American group working with Walter Reed demonstrated the transmission of yellow fever by <i>Aedes aegypti</i>
1903	The English scientists W. B. Leishman and C. Donovan independently described <i>Leishmania donovani</i> , the agent of Kala-azar disease
1904	In Cairo the German helminthologist Arthur Loos (1861–1923) discovered the transmission of the hookworm
1906	The American physician Howard T. Ricketts (1878–1910) recorded the tick <i>Dermacentor andersoni</i> as being a vector of the agents of the Rocky Mountain spotted fever
1906	The German zoologist and discoverer of the agent of syphilis Fritz Schaudium (1871–1906) described <i>Entamoeba histolytica</i> as a human parasite
1907	The American E. E. Tyzzer described stages of the genus <i>Cryptosporidium</i>
1907	The German chemist Paul Ehrlich (1854–1925) – the father of chemotherapy – proposed the drug try-pan-red against trypanosomiasis (Nobel Prize 1908)
1908	In North Africa the French military doctors Charles Nicolle (1866–1936) and L. H. Manceaux described <i>Toxoplasma gondii</i> in a rodent
1909	The Br azilian Carlos Chagas (1879–1934) discovered the life cycle of <i>Trypanosoma cruzi</i> and described <i>Pneumocystis carinii</i>
1909	Teams working with the Frenchman Charles Nicolle (1866–1936) (Tunis) and the American H.T. Ricketts (Mexico) proved that the louse <i>Pediculus humanus corporis</i> is a vector of the typhus-causing rickettsia
1910	The Italian Carini discovers <i>Pneumocystis carinii</i> in rats
1914	The Japanese scientists M. Miyairi and M. Suzuki worked out the life cycle of <i>Schistosoma japonicum</i>
1916–1920	Development of Suramin (B205) against trypanosomiasis (Bayer Co., Germany)
1917	The Austrian psychiatrist Julius Wagner Ritter von Jauregg (1857–1940) tested a live vaccination using <i>Plasmodium vivax</i> -stages (Nobel Prize 1927)
1925	The English natural scientist D. Keilin elucidated the electron cascade (cytochrome) system while using parasitic insects and worms as models

(continued)

Historical Landmarks, Table 1 (continued)

1934	Discovery of chloroquine as a malaricidal drug at Bayer Co. (Wuppertal, Germany)
1938	The German scientists Helmut and Ernst Ruska developed the transmission electron microscope at Siemens Co. (Berlin) (Nobel Prize 1985)
1939	Sulfonamides were introduced as anticoccidial drugs and the Nobel Prize was awarded to their discoverer Gerhard Domagk (1895–1964) (Bayer Co., Leverkusen, Germany)
1944	Erich Reichenow and N. Mudrow (Leverkusen, Germany) demonstrated the liver stages of avian malaria
1950	In the USA C. Bueding demonstrated the carbohydrate metabolism in <i>Schistosoma mansoni</i>
1953	The Americans J.D. Watson and F.H.C. Crick described the structure of DNA
1955	DDT, which had been developed in 1939 by the Swiss Paul Müller , was introduced as an insecticide
1956	The English scientists P.C.C. Garnham and S. Short demonstrated the liver stages of <i>Plasmodium</i> within humans
1959	The English natural scientist J.D. Smyth and J.A. Clegg elucidated the egg shell formation in flatworms
1960	Erich Scholtyseck (Bonn, Germany) and Datus Hammond (Logan, Utah) started systematical electron microscopic studies on Coccidia
1961	The American L.S. Diamond cultured <i>Entamoeba histolytica</i> axenically
1961	First reports on chloroquine resistance in Asia and Africa
1963	The Americans F.M. Fischer and R.M. Sanborn demonstrated that the microsporidian <i>Nosema</i> produces juvenile hormones for its insect host
1963	The Americans C.P. Read , A.H. Rothman , and J.E. Simmons demonstrated the basics of the membrane transport in cestodes
1964	The American R. Damian proved molecular mimicry in schistosomes
1965	The Australian W.P. Rogers discovered the role of enzymes in the molting of nematodes
1966	Introduction of benzimidazoles as broad spectrum anthelmintics
1969	The American Jack Frenkel (Kansas) and the Indian J.P. Dubey together described the cat as final host of <i>Toxoplasma gondii</i> . Work and Hutchinson (Scotland) and Overdule (Holland) independently achieved the same result
1972–1977	German research teams led by Micheal Rommel , Alfred Otto Heydorn and Heinz Mehlhorn discovered and described the life cycles of several <i>Sarcocystis</i> species and related cyst forming species
1975	Georg Köhler and J. Milstein developed the hybridoma technique for the production of monoclonal antibodies (Nobel Prize 1986)
1975	The English biologist C. Cross characterized the glycoprotein surface coat of trypanosomes
1975–1978	German research teams led by Eberhard Schein , Karl Friedhoff , and Heinz Mehlhorn discovered the complete life cycles of 10 <i>Theileria</i> and <i>Babesia</i> species
1976	The Americans Trager and Jensen succeeded in establishing continuous <i>in vitro</i> cultures of <i>Plasmodium falciparum</i>
1976	The Americans C.H. Zierdt and J. Tan introduced <i>Blastocystis</i> as a parasite
1978	The Scottish scientists Keith Vickerman and G.A.M. Cross demonstrated antigenic variation in the surface coat of trypanosomes
1981	Introduction of ivermectin
1981	The Swiss Burgdorfer recognized <i>Ixodes</i> ticks as vectors of <i>Borrelia</i> bacteria, the agent of Lyme disease
1982	American scientists defined the first malaria antigen-circumsporozoite antigen
1984	The threat of AIDS was growing and the importance of opportunistic parasites became recognized
1985	Application of PFGE to parasitological problems
1986	Recognition of the importance of zymodemes for the identification of strains of <i>Trypanosoma cruzi</i>
1987	Use of DNA probes in the field
1988	Application of DNA-amplification techniques in parasitology
1988	The Colombian microbiologist M.E. Pattarroyo presented a synthetic vaccine against <i>Plasmodium falciparum</i>
1989	RNA editing in parasites
1989	RNA-editing was found to occur in trypanosomes

(continued)

Historical Landmarks, Table 1 (continued)

1990	Possible role of transgenic mosquitoes in control measures
1990	The reasons for sequestration in <i>Plasmodium falciparum</i> were detected
1991	Cross-regulation of Th1 and Th2 subsets in parasitic infections
1991	The function of nitric oxide in human malaria and other parasitic infections was detected
1992	Potential of understanding genomes of parasites and vectors
1993	Avermectins and management of arthropods of medical and veterinary importance
1993	M.E. Pattarroyo reported on first successful malaria vaccine trials in South America (failures occurred later)
1994	HIV-AIDS and leishmaniasis
1995	Trials of the SPf66 malaria vaccine in humans
1996	Combination therapy for malaria
1997	Global mapping of filariasis
1998	Climate change and vector-borne diseases
1999	Roll Back Malaria initiative
2000	<i>Wolbachia</i> in filarial worms as a target for chemotherapy
2000	<i>Plasmodium falciparum</i> genome completed
2001	Apoptosis of intracellular protozoa
2002	Genetic analysis of arthropod blood meals
2003	Transgenic mosqzitoes and malaria control
2003	Human genome completed
2004	DNA microarray analysis of protozoan gene expression Application of DNA fingerprinting to forensic science

More recent findings are not listed, since several have to be confirmed and/or enlarged in their basic elements. Of course, many other discoveries – especially in the last decades – are surely worth citing. Their importance for the ongoing struggle against parasites will, however, become clearer in the future

HIV

Human immunodeficiency virus.

regression of diseases due to infections with opportunistic parasites. This is not only explainable by support of the immune system (e.g., Indovir may reduce *Cryptosporidium*-infections up to 100%, *Toxoplasma*-infections up to 63 %).

HIV Interactions

Many parasites grow much better in hosts that are HIV-infected (► [Opportunistic Agents](#)). Some like ► [Leishmania](#) spp. induce the activation of HIV in latently infected monozytic and T cells.

Hoferellus

Genus of Myxozoa of fish.

HIV Protease Inhibitors

The highly active antiretroviral therapy (HAART) in HIV-patients has shown a significant parallel

Hoferellus cyprini

Species of Myxospora in carps.

Hohorstiella lata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Mallophagan species of doves. The genus name honors the German parasitologist Hohorst, who fully described the life cycle of ► *Dicrocoelium dendriticum* while working at Hoechst AG Research Center, Frankfurt, Germany.

Holarctis

Name

Greek: *holos* = total, *arctos* = north.

Zoogeographical region with typical animals and plants accommodated at moderate and cold climate around the northern pole.

Holarktikos crassiceps

Mallophagan species of goats.

Hologamy

From Greek: *holos* = total, *gamein* = mating. Total fusion of two individuals (e.g., in protozoans).

Hologonic Ovaries

In hologonic ovaries which are found in trichurid ► *nematodes* the oogonia cover the entire wall of the ovarian tube. The germ cells develop via the various stages of oogenesis while moving from

the wall towards the lumen of the ovary (► *Nematodes/Reproductive Organs*).

Hologonic Testes

The hologonic type of ► *testis* where the spermatogonia line the wall of the testis is found in trichurid ► *nematodes*; moreover, spermatogenesis occurs during migration towards the lumen of the testis (► *Nematodes/Reproductive Organs*).

Holometabolous Development

This type of development, which is the most common in insects, is also found in large groups of ectoparasites (e.g., ► *Diptera*, ► *Fleas*, ► *Diptera*, Fig. 1, ► *Fleas*, Fig. 2, ► *Mosquitoes*, Fig. 1). In general different types of developmental stages occur during a holometabolous life cycle: larva, ► *pupa*, and adult (► *imago*). Larvae, which hatch from the egg and which may undergo a species-specific number of molts, are completely different from the adults. They feed on other substrates, in general lack the body appendages of adults (e.g., antennae, wings, mouthparts, legs), and often have only rudimentary eyes. The pupae are nonfeeding, very often remain quiescent (an exception are the motile pupae of ► *Mosquitoes*, see ► *Mosquitoes*, Fig. 1), and are in general in a thickened ► *cocoon* or ► *puparium*. Inside the puparial cover a complete reorganization of the insect's body occurs, leading to the final production of the adult male or female, which leave the pupa by typical opening mechanisms.

In general, the adults (*imago*) of ectoparasites feed on their hosts. In flies, tabanids, and fleas both sexes feed on the host's blood or body fluids, whereas in mosquitoes only the females take up blood (besides nectar) in order to produce viable eggs. The mouthparts (► *Insects*, Figs. 7–9) are species-specific as are the mating processes, which start soon after hatching from the puparial enclosure.

Homidium

Salt Trypanocidal Drugs.

Homologaster

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of digenetic trematodes from ruminants, the species of which are characterized by a broad amount of ventral papillae that are situated before the terminal sucker (acetabulum).

Homology

Common ancestry of two genes (characters, genes, positions, etc.).

Homoxeny

From Greek: *homos* = identical, *xenos* = foreign. Uniform development, development in one host-type.

Hooks

Holdfast organs of ► [Acanthocephala](#), some digenetic Trematodes, ► [Cestodes](#), ► [Monogenea](#), ► [Pentastomida](#).

Hookworm Disease

Pathology

Hookworm disease is produced by *Ancylostoma duodenale*, ► [Necator americanus](#), and several other species (► [Hookworms](#)). The larvae live in moist soil and enter the skin, giving rise to allergic dermatitis with a papular and sometimes vesicular focal rash that is intensely pruritic and is sometimes referred to as “ground ► [itch](#)”. The larvae enter the blood stream, get to the lungs where they may give rise to focal hemorrhages and to allergic ► [pneumonia](#). The larvae migrate up the bronchial tree to the pharynx and are swallowed. They reach adulthood in the upper small intestine where they attach to the mucosa with their powerful buccal capsule enclosing a tag of mucosa from which they draw blood. This may be accompanied by ► [abdominal pain](#) after 35–40 days. From time to time the worm moves to another site, sometimes leaving the microscopic ► [ulcer](#) to bleed until the vessels thrombose and the site heals. With heavy infection anemia develops. Because the worms take in more blood than they assimilate; black stools, or melena, are common, but some of the iron lost is resorbed in the intestine.

Immune Responses

Data indicate that a Th2-dominated immune response acts to reduce the weight and ► [fecundity](#) of ► [hookworms](#) like *Ancylostoma duodenale* and *Necator americanus* in the human gut. Parasite specific IgE and ► [eosinophilia](#) may be involved in host protection. In elder patients there is significant negative correlation between antilarval IgG antibodies and

parasite burden. The fact that human hookworms nevertheless survive in an immunological hostile host for many years may be best explained by efficient escape mechanisms preventing the immune system from exerting its full effects. Several molecules secreted by hookworms have a potential to inhibit or antagonize the immune system of the host. In ► *Ancylostoma* species, the neutrophil inhibitory factor (NIF), a glycoprotein of 41 kDa potently inhibits CD11b/CD18 dependent neutrophil activation and adherence to vascular endothelium. Since *Necator americanus* lacks NIF it may rely on acetylcholinesterase, glutathion-S-transferase, and superoxide dismutase to suppress inflammation. Acetylcholinesterase not only inhibits gut peristalsis but may also suppress the release of inflammatory cytokines by lymphocytes stimulated via their muscarinic receptors. Secreted glutathion-S-transferase, and superoxide dismutase may represent protective mechanisms of the hookworms against reactive oxygen intermediates produced by activated leukocytes in the gut. An IgA protease present in *Necator americanus* has the potential to produce IgA Fab fragments capable of blocking complement or phagocytic attack mediated by intact IgG or IgM. Since secretory IgA provides a potent signal for eosinophil degranulation, the secretion of an IgA protease would be beneficial to the parasite also on this level.

Targets for Intervention

Both *Ancylostoma duodenale* and *Necator americanus* require specific ► [environmental conditions](#) for their larvae to hatch and become ensheathed, rhabditiform, infective organisms that will actively enter a new host through the skin, usually that of the feet or lower part

Hookworm Disease, Fig. 1 Targets and approaches for the control of hookworm disease

of the legs. Most of the infections are contracted in the peridomestic environment. Figure 1 indicates the infected host, the contaminated environment, and the infection cycle as targets of intervention. Suitable approaches to control include the detection and treatment of infected persons, the safe disposal of feces, rigorous environmental sanitation, and wearing shoes as a means of avoiding skin contact with contaminated soil.

Main clinical symptoms: ► [Pruritus](#), bronchitis, eosinophilia, red-diarrhea, fever, ► [anemia](#), cachexia, breakdown of circulation.

Incubation period: Dermatitis: 4 h, intestinal symptoms: 2 weeks.

Prepatent period: 5–6 weeks.

Patent period: 20 years.

Diagnosis: Microscopic determination of eggs in fecal samples (Fig. 2).

Hookworm Disease, Fig. 2 Egg of *Ancylostoma duodenale* obtained by M.I.F. concentration method

Prophylaxis: Use solid shoes in endemic regions and avoid human feces.

Therapy: Treatment see entry “Nematocidal Drugs”.

Hookworm Vaccine

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Since all stages of the hookworms suck blood, a vaccine protecting from hookworm diseases seems possible. The first attempts started by irradiation of larvae using 40,000 röntgens of X-ray. Based on these and other experiments, the Human Hookworm Vaccine Initiative (HHVI) was launched supported by the Bill and Melinda Gates Foundation. As a follow-up, two human Na-ASP-Z vaccines were clinically tested with medium success, and in 2010, the works on next-generation human vaccines were started using Na-APR-1 and Na-GST-1. These target

proteins seem to induce lower hypersensitivity reactions.

Hookworms of Animals, Fig. 3 Scanning electron micrograph of the mouthpart of *Uncinaria stenocephala*. Note two cutting plates without teeth

which parasitize in the small intestine of their hosts, where they are fixed at the wall by help of their specific teeth (Figs. 2 and 3), suck permanently blood. The males are characterized by a terminal hold-fast system (called bursa copulatrix, Fig. 4), which becomes attached around the female genital opening, so that sperms can be injected there. Copulation is permanent while both sexes are attached to the intestinal wall and suck blood (Fig. 5). The females and males are of different size (Table 1), so that couples form a

Y-shape during copulation (Fig. 1). Females excrete the eggs in an early stage of development containing 6–9 blastomeres (Fig. 5). The larva 1 develops inside the egg within temperature-dependent time and hatches from the egg (Fig. 1). At temperatures of about 20 °C it takes 15 days, until the infectious larva 3 is formed after two molts. This larva 3 remains in the sheath of the larva 2 and aggregates together with others at the tip of grass or other ground plants (Fig. 1). If a host touches this “tree of larvae” the larvae enter its skin and migrate via heart-lung-trachea-esophagus to their final destination inside the small intestine (mostly jejunum), where each worm reaches maturity and sucks about 0.1 ml of blood per day. If humans come into contact with such larvae, infection may occur!

Hookworms of Animals, Fig. 1 (continued) 9–10 L₃ live in the upper few millimeters of soil, migrate to the surface, and are often found in groups of thousands on the soil or on plants (moving synchronously). 11 Infection of final hosts occurs when L₃ contacts the skin and burrows into it. After a heart-lung-trachea passage the L₃ reach the intestine, molt twice, and become sexually mature (In some species transplacental transmission of L₃ or transmission in mother’s milk is possible). 12 If a human becomes invaded

by L₃ of a species or strain that normally matures in animals (e.g., *A. caninum*, *A. braziliense*) the larvae migrate for months through the cutaneous layers, leading to a disease called “▶ [creeping eruption](#)”. Hookworms of Animals, Fig. 6 Human arm showing pathways of several larvae migrans

Hookworms of Animals, Fig. 7 Light micrograph of a thin-shelled hookworm egg during cleavage

Symptoms of Disease: (Hookworm Disease)

Animals start licking at the penetration sites, edemas occur at the skin, rather soon start diarrheas, loss of weight, anemia, phases of obstipation, flatulence, and pneumonia. Young animals may die in cases of infections with large numbers of larvae 3. **Humans:** Symptoms depend on the organ which is affected by wandering larvae (= larva migrans) as well on the severity of the infection as on the amount of migrating larvae.

Humans can be infected by larvae of hookworms of animals, which then introduce the symptoms of the larva migranscutanea (Fig. 6).

Diagnosis

Bloody feces and microscopic demonstration of the thin-shelled eggs (Fig. 7).

Infection

Percutaneous penetration of free living larvae 3 (Fig. 8), also galactogeneous infections are possible as well as ingestion of paratenic hosts.

Prophylaxis

Regular cleaning of stables from feces in order to avoid hatch of larvae from embryonated eggs (Table 1).

Incubation Period

It takes about 8 days, when larvae pass through lung into the trachea.

Prepatent Period

Depends on the species and on the way of infection; e.g., it takes 15–18 days in the case of *A. caninum* in case of percutaneous infection until maturity is reached and first eggs are excreted. In case of *U. stenocephala* prepatency takes 13–15 days, in *A. tubaeforme* 18–23 days, or in cases of *Bunostomum* 49–59 days, and *Globocephalus* 26 up to 36 days.

Hookworms of Animals,
Fig. 8 Light micrograph of
 a sheathed larva 3

H

Patency

Years, at least 1 year.

Therapy

See Nematocidal drugs. Medicaments such as mebendazole, moxidectin, selamectin, emodepsid have been proven high curing rates. Use depends on regional allowances.

Hookworms of Humans

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Ancylostomaduodenale*, *A. ceylanicum*, *Necatoramericanum

Name

Greek: *ankylos* = crooked, bent; *stoma* = mouth;
 Latin: *duodenalis* = 12-fold, belonging to the duodenum, most upper portion of the small intestine; *necator* = killer; *ceylanicum* = coming from Ceylon.

Geographic Distribution/Epidemiology

Hookworms of the species *A. duodenale* occur in humid-warm regions between 30° South and 45°

North (North Africa, North and South Asia); *N. americanus* are found in America, Central Africa, South and East Asia. Due to tourism and globalization human cases occur worldwide. A local species (*A. ceylanicum*) occurs in Taiwan, South Asia, and Surinam.

Morphology/Life Cycle

The adults of these three nematode species reach in both sexes a length of about 1 cm and can be differentiated from each other morphologically (Figs. 1, 2, 3, 4, 5, and 6, Table 1) and by means of molecular biological criteria. However, the thin-walled eggs, which measure $60 \times 40 \mu\text{m}$ (Fig. 6), look similar and thus cannot be used for species determination. Females of *A. duodenale* produce about 9,000 eggs per day and *A. americanus* about 10,000–15,000. Both males and females suck blood in the jejunum (mostly in copula position, see Fig. 1). They ingest blood not only for feeding but also for obtaining oxygen.

Thus they take up larger amounts than needed for feeding so that often – in case of severe infections – the feces of the patients may appear reddish-blackish. The eggs in fresh feces of humans contain only 2–8 cells (Fig. 1); however, under optimal conditions the rhabditiform larva 1 is developed within 2–3 days. After hatching this larva grows up via two molts within 5–7 days to the infectious larva 3. This stage reaches a length of 500–650 μm and remains enclosed by the sheath of the larva 2 (thus this stage is described “sheathed larva”). Infectious larvae creep up to the top of grass and form a cluster, which is described as “larval tree.” This phenomenon leads to the fact that a host is mostly infected by several larvae at the same time, increasing the chance that both sexes enter the host at the same time and new progeny can be produced. During penetration into the skin the larval sheath is striped off and the larva 3 starts a heart-lung-trachea wandering and finally reaches within 3–7

Hookworms of Humans,

Hookworms of Humans, Fig. 3 Scanning electron micrograph of the mouth of *A. duodenale*. Note that this worm possesses two teeth plates each with two hooks

Hookworms of Humans, Fig. 4 Scanning electron micrograph of the mouth of *Necator americanus*

Symptoms of Disease:(Ancylostomatiasis, Necatoriasis, Hookworm Disease, Miner's Disease)

days the intestine after passing the esophagus and stomach. Via larval stage 4 and a premature stage worms reach maturity about 4–6 weeks after skin penetration.

About 20–25 % of the human world population are at least once in their lifetime infected by hookworms. This occurs mainly in subtropical and tropical regions. But also in cooler climates hookworms may occur or had occurred in the past. The name “tunnel disease” or “miner's disease” points to this fact, since still at the beginning of the last century (due to lacking chemotherapy)

larvae were found in workers in mines and tunnels, which always offer higher temperatures than occur outside. Infections with less than 30 worms of the species *N. americanus*, which each ingest 0.03 μ l blood per meal, remains mostly hidden. However, infections with 100–150 adults lead to significant

symptoms, and more than 1,000 worms may be life threatening. Since each *A. duodenale* worm sucks 10 times more blood than a *N. americanus* worm, already infections with only 100 worms lead to symptoms of severe anemia. Since the worms often change their sucking place, in addition blood is wasted there for a while increasing the total blood loss. Infections with hookworms lead to the following symptoms:

- **Penetration phase:** Itching, formation of papulae at the penetration sites.
- **Lung passage:** Bronchitis, lymphnode swellings, eosinophilia.
- **Acute disease:** Reddish-black stools, high fever, high eosinophilia, if massive amounts of worms occur.
- **Chronic disease:** The type of disease is also dangerous, since worms live up to 20 years. Important symptoms are stomach and intestinal malfunctions, slight fever, occult blood in stool, phases of obstipation and diarrhea, increasing anemia, cachexia, weakness, and often death due to exhaustion.

Hookworms of Humans, Fig. 5 Scanning electron micrograph of the posterior end of a male hookworm, which is provided with a hand-like bursa copulatrix, that becomes attached around the female's genital opening

About 100,000 persons die per year as a consequence of an infestation with hookworms

Hookworms of Humans, Fig. 6 Light micrograph of the bursa copulatrix of a hookworm

Hookworms of Humans, Table 1 Characteristics of the hookworms *Ancylostoma duodenale* and *Necator americanus*

Characteristics	<i>Ancylostoma duodenale</i>	<i>Necator americanus</i>
Mouth opening	4 visible teeth (2 on each plate)	2 cutting plates, no separate teeth
Posterior end of females	With a pointed tip	Without a pointed tip
Position of the female genital opening	Behind the center of the body	Before the center of the body
2 spicula (of males)	Never melted	Connected at the tip with reverse hooks

especially in regions with poor hygiene conditions. Mainly children are endangered, since anemia stops development of a healthy body.

Diagnosis

The eggs (90 × 60 μm) of the hookworms (Fig. 7) can be isolated by concentration methods (► [M.I.F.C.](#); ► [S.A.F.C](#)) and easily differentiated by their contents (= only 2–8 cells) from similar-looking eggs of ► [Trichostrongylus](#) species or ► [Ternidens deminutus](#), which show at least 32 or 64 cells in freshly excreted eggs.

Infection

Penetration of free larvae 3 into the skin. Due to lacking immunity repeated infections are possible (Fig. 8).

Prophylaxis

Use stabile, closed shoes in endemic regions; avoid contact to human and animal feces. **Attention:** In laboratory larvae may hatch also from eggs, thus intensive cleaning of examination vessels is strictly recommended. Feces should never be stored at fresh status in open vessels.

Incubation Period

Few hours after skin penetration dermatitis may occur. About 2 weeks later first intestinal symptoms appear.

Hookworms of Humans, Fig. 7 Light micrograph of an egg of *Ancylostoma duodenale* at a progressing stage of development

Prepatent Period

Five to six weeks.

Patency

Up to 20 years.

Treatment

Application of mebendazole (2 × 100 mg) for 3–5 days or albendazole (1 × 400 mg), children under 2 years (15 mg/kg body weight). However, also other anthelmintics are effective (ivermectin, levamisole, pyrantel, or bephenicum); however, many of them are not registered in several countries. In case of anemia also substitution of iron is needed as well as eventual blood transfusions in severe cases.

See ► [Nematomorpha](#), which are named due to their tiny diameters in contrast to their considerable lengths.

Host Behavior

General Information

Host behavior can be modified in various ways by parasites, for instance just because of debilitation. However, the most interesting alterations are related to the ► [extended phenotype](#).

In the last 20 years, an increasing number of “manipulations” of host behavior by parasites have been reported. These manipulations increase the chances of the life cycle being completed.

The case of the “brainworm” which manipulates ant behaviour was one of the first cases to be described in detail. ► [Dicrocoelium dendriticum](#) is a trematode which develops in three successive hosts: a terrestrial gastropod, an ant, and a mammal (usually a sheep). ► [Cercariae](#) are produced in the snail and emitted in small mucus balls which attract ants and are eaten by them. For the life cycle to be completed, the ant must be then ingested by a sheep. One of the ingested cercariae makes its way towards the brain of the ant and provokes a drastic change in the behavior of its host: “whereas an uninfected ant would normally retreat into its nest when it became cold, infected ants climb to the top of grass stems, clamp their

► [jaws](#) in the plant and remain immobile as if asleep.” This “abnormal” behavior increases considerably the probability of the infected ants being eaten by sheep. It is also remarkable that the infected ant, if not eaten, goes down to its nest during the hot period of the day (which prevents it from dessication) and returns at night to its position at the top of stems.

Such adaptive processes, which increase the probability of a parasite completing its life-cycle by modifying host behavior, are part of a more general aspect of parasite adaptations, called favorisation.

Host Cell Invasion

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

General Information

When a parasite comes into contact with a potential host cell, two series of events may occur which lead to intracellular parasitism. First comes a recognition step which enables a suitable close association between both partners, and then comes the internalization of the organism within the host cell. The mechanisms of recognition are far from being entirely elucidated, as well as the ones by which entry occurs. Data have been obtained, however, which show that the different parasite groups have evolved different strategies toward these goals.

A major question when dealing with host cell invasion by a pathogen is to decide whether this one actively enters a cell or whether it is engulfed by the process called phagocytosis. The matter is

rather clear with those parasites which force their way through the plasma membrane of the host cell or fuse their membrane with it; it is more confusing when internalization occurs within a ► **parasitophorous vacuole**, the membrane of which is continuous with the host cell ► **plasma-lemma** during the whole invasion process, as is the case with most protozoan parasites. Moreover, when a parasite uses phagocytosis to gain access into a cell, another important issue is its behavior facing the fate of a phagosome, i.e., fusion with a lysosome and exposure to a cocktail of lytic enzymes which are supposed to digest the

phagosomal contents. Parasites seem to have also evolved various ways of escaping this fatal outcome, as will be described below. Different invasion processes which occur among intracellular eukaryotic pathogens are depicted in Fig. 1.

Because of their medical interest, host cell invasion by Apicomplexan zoites (e.g., ► **Plasmodium**, *Toxoplasma*, ► **Eimeria**, ► **Sarcocystis**, or ► **Piroplasms**) has been studied to a great extent (► **Apicomplexa**, ► **Host Cell Invasion**).

In contrast, little morphological data are available on the invasion of host cells by kinetoplastids. More studies deal with the ways these organisms escape the phagosome lysosome fusion (► **Trypanosoma/Host Cell Invasion**, ► **Leishmania/Host Cell Invasion**). Although rather poorly known, the mechanism of cell invasion by ► **Microsporidia** has very peculiar characteristics. ► **Microsporidia** self-inject into their host cell by devaginating a membranous organelle (► **Polar Tube**) which forces its way through the host cell plasmalemma and through which the parasite ► **cytoplasm** moves into the recipient cell (Fig. 1). Invasion is thus intrusive: this is the only case known among intracellular parasitic ► **protozoa** where parasite development may occur either in the cytoplasm of the cell or within a parasitophorous vacuole, but whether this ► **vacuole** forms at invasion or later is not known.

Host Cell Invasion, Fig. 1 Invasion processes observed among different intracellular pathogens. 1 Invasion by phagocytosis, parasite development in phagolysosomes (e.g., ► **Leishmania** spp.). 2 Invasion by “phagocytosis,” escape of the parasite into the host cell cytoplasm (e.g., *Trypanosoma cruzi*). 3, 4 Active invasion of ► **Apicomplexa**, characterized by a ► **moving junction** and the development of the parasitophorous vacuole. An originality of piroplasms (e.g., ► **Babesia**) is the disintegration of the parasitophorous vacuole membrane soon after invasion, the parasite then lying directly within the erythrocytic stroma (3). Other Apicomplexa complete their ► **schizogony** within a parasitophorous vacuole after inhibition of fusion with ► **lysosomes** (4). 5 Invasion through the host cell plasmalemma (Microsporidia).

Host Demography

The impact of parasites on host demography was underestimated by ecologists for a long time but, during the last 20 years, several studies have demonstrated that parasites play a prominent role in the regulation and sometimes even breakdowns of their host populations.

Among the studies on the relationship between the parasitic load and the demography of the hosts, the following are especially demonstrative.

In Scotland, important variations in the population densities of the grouse *Lagopus lagopus scoticus* depend at least in part on the abundance of the nematode *Trichostrongylus tenuis*, which lives by thousands in the caeca of the bird. The

years when climatic conditions favour the survival of the larvae of the nematode in the open air, the grouse experience increased predation and loss of ► **fecundity**.

Similarly, another nematode, *Obeliscoides cuniculi*, makes the snowshoe hare *Lepus americanus* vulnerable to its predators. Individuals which are treated by an anti-helminthic (ivermectin) are two to three times less often captured by predators than controls.

However, parasites are not always detrimental to their hosts. This happens when parasites interfere with competition between hosts. A parasite is capable of modifying the status of competition between free-living species, as soon as the species in competition are differently affected by this parasite. For instance, the fruit flies *Drosophila melanogaster* and *D. simulans*, species morphologically similar but genetically isolated, are attacked, at the larval stage, by the parasitoid wasp *Leptopilina boulardi*. Experiments by Boulétreau et al. have demonstrated that, when *D. melanogaster* and *D. simulans* are grown together in equal numbers at 25 °C, *D. melanogaster* eliminates *D. simulans* in a few weeks. However, when the parasitic wasp is added to the system, an equilibrium becomes established, and the species of *Drosophila* coexist. Boulétreau et al. explained this result by a different receptivity of the 2 *Drosophila* to the parasitoid, which parasitizes *D. melanogaster* more frequently than *D. simulans*. Field studies in African oases have demonstrated that, the more abundant the wasp is, the more an equilibrium between the species of fruit flies is realised: the conclusion is that a parasite may be detrimental to individuals, but beneficial to the population (in this example, any individual of *D. simulans* which is infested by *Leptopilina boulardi* is finally killed by the parasite, but *D. simulans* can compete successfully with *D. melanogaster* only where the parasite is present).

Freeland thinks that a species may invade an ecosystem only if its susceptibility to the local parasites is lower than that of the related autochthonous species. This case is probably rather rare because the immigrant, being in contact with the parasite for the first time, may have limited defences. This means

that certain parasites can contribute to maintaining the composition of faunas (biodiversity), by protecting them from invasions. A classical example is that of the nematode *Parelaphostrongylus tenuis*, a parasite of the North American white-tailed deer *Odocoileus virginianus*, which reduces the competition of its host with other ungulates. For instance, the moose *Alces alces* is more susceptible to the parasite than the white-tail deer and experiences important mortality rates when it invades the territories of the white-tailed deer.

The same kind of “protection by parasites” can play a role within a given species, between populations of this species. It is probable that ► **malaria** protected Africans from colonisation until the discovery of quinine and that, nowadays, trypanosomes protect native African ungulates from the introduction of alien species.

Because the impact of parasites on the competition between hosts is often unpredictable, the consequences of introduction of allochthonous species with their parasites can be dramatic: the Caspian sturgeon *Acipenser stellatus* was introduced 40 years ago in the Aral Sea with its monogenean parasite *Nitzschia sturionis* which passed onto the local sturgeon *A. nudiiventris*. There this new parasite provoked disastrous mortality rates in the autochthonous species. It is not impossible that the extinction of some vertebrates in the course of geologic times were due partly to parasites.

Finally, the history of the conquest of Latin America is perhaps the best example of the impact of “new” parasites on host populations. Black estimates that more than 50 million native Americans died from pathogens introduced by the invaders. This recalls the sentence of Haldane: “a non-specific parasite to which partial immunity has been acquired, is a powerful competitive weapon.”

Host Endocrine System

General Information

A possible strategy for a successful adaptation of a parasite to its host is the induction of conditions favourable for its own development and

metabolism by manipulating the endocrine system of the host. This same goal can also be reached by producing hormones which are similar to host hormones and which mimic their actions (► [Gastrointestinal Hormones](#), ► [Growth Factors](#)). Modification of the endocrine system of the host by a parasite leading to favourable conditions has indeed been found in a variety of host-parasite interactions in both invertebrates and vertebrates and practically every hormone system in a host might be involved. Changes in hormone titres of the host may not only be seen under the aspect of favourable for the parasite but may also represent adaptations of the host to a disadvantageous condition. For example, the reduced level of thyroxine in severe falciparum malaria patients is interpreted as an adaptation of men to accelerated catabolism. One also has to keep in mind, that one hormone might act in various ways, may be dependent on the parasite species. In the case of nematode-infected mammals thyroxine exerts its influence presumably via the immune system of the host.

Manipulation Mechanisms

Manipulation of the host's endocrine system in order to improve the living conditions for the parasite involves several mechanisms:

- Maintenance of an adequate food and energy supply (► [Ecdysteroids](#), ► [Gastrointestinal Hormones](#), ► [Growth Factors](#), ► [Insulin](#), ► [Juvenile Hormones](#)).
- Induction of immunosuppression, not only by interfering with immunomodulatory steroid hormones (► [Sex Steroid Hormones](#), ► [Glucocorticoids](#)), but also by the induction of specific defence molecules. A newly described Ig-superfamily member from the snail *Lymnaea stagnalis* is downregulated during the course of parasitosis with the trematode ► [Trichobilharzia ocellata](#).
- Induction of analgesia in the host (► [Opioids](#)).
- Control of the speed of development, an adequate body size and reproduction of the host. These diverse effects might be brought about by

one and the same hormone. For example, higher juvenile hormone concentrations in larval stages of insects increase body size, prolong larval life and prevent reproduction, whereas in females ► [juvenile hormones](#) induce vitellogenin synthesis in the fat body and facilitate vitellogenin uptake into ► [oocytes](#). Both processes are inhibited in females if they are infected by metacestodes. In the *Lymnaea-Trichobilharzia* system mentioned above, not only is immunosuppression induced by the ► [cercariae](#) but also the synthesis and/or release of a peptide, called schistosomin, which has cytokin-like functions without being a cytokine and which leads to ► [castration](#) and giant growth in the snail host (► [Ecdysteroids](#), ► [Growth Factors](#), ► [Juvenile Hormones](#)).

All these processes are under hormonal control and may be the result of a rapid and direct change in gene expression in the host, evoked by the parasite. Of course these processes can also be regulated by other factors and they may not be realised simultaneously. It is also not clear in all instances whether the changes in the host's hormonal system are specific or general stress reactions.

Host Finding

Wilfried Haas

Institut für Zoologie 1, Universität Erlangen-Nürnberg, Erlangen, Germany

Many parasite stages reach and infect their hosts, and an increasing amount of research is concerned with the question of how the parasites find and recognize their hosts. In most cases where host-finding behavior has been analyzed in some detail, it has been found to consist of a series of different behavioral phases. In each of these phases the parasites may respond to different environmental or host signals, a fact which often complicates the experimental analysis of host-finding behavior. Most information on the complex nature of host finding is available in ► [helminth](#) parasites for digenae miracidia and ► [cercariae](#) (► [Digenea](#)),

and ► **nematode** larvae, and in bloodsucking arthropods for ► **mosquitoes**, tsetse flies and ► **ticks** (for details see *Host Finding* in the entry of the respective group).

The mechanisms of host finding and host recognition in these better-studied parasite groups support the following views. Most parasites which actively reach and infect their hosts have evolved very complex behavior patterns for finding their hosts and most of them achieve a narrow range of host-specificity. This is also true for stages which are produced in very large numbers (e.g., trematode cercariae). Another typical characteristic of host finding is a high diversity of host recognition strategies. Normally, each species finds and identifies its host with mechanisms and in response to host signals that differ from those of other species, even when these attack the same host genera. The high complexity, specificity, and diversity of host recognition strategies suggest that host finding and host recognition are important determinants in the evolution of parasitism.

Host Hormone Effects on Parasites

Some parasites are considerably affected in their development by host hormones (Table 1).

Host Manipulation by *Toxoplasma gondii*

Jaroslav Flegr
Department of Biology, Faculty of Science,
Charles University in Prague, Prague, Czech
Republic

Many parasites have evolved adaptive mechanisms for manipulation of host phenotypes, including behavior, to increase their chances of transmission from infected to noninfected hosts (Holmes and Bethel 1972). Very conspicuous behavioral changes are induced by parasites that are transmitted from intermediate to definitive host by predation because induced behavioral patterns increase biological fitness of the manipulating parasite but decrease fitness of the carrier – the infected animal. An already classical model for studying manipulative activity of parasites is the heteroxenous coccidian *Toxoplasma gondii*, whose life cycle includes transmission from intermediate host (any warm-blooded animal) to definitive host (any feline species) by predation. *Toxoplasma* is known to modify not only the behavior of its intermediate animal hosts but also the behavior and personality of infected humans.

Host Hormone Effects on Parasites, Table 1 Examples of host hormone effects

Parasite	Hormone	Parasite stage	Effects
<i>Entamoeba histolytica</i>	Cortisol	Trophozoites	↑ Reproduction, ↑ metabolic activity
<i>Leishmania mexicana</i>	GM-CSF	Promastigotes	↑ Growth
<i>Trypanosoma cruzi</i>	EGF	Amastigotes	↑ Growth, ↑ reproduction, ↑ metabolic activity
<i>Plasmodium falciparum</i>	Cortisol	Merozoites	↑ Growth, ↑ reproduction
<i>Schistosoma mansoni</i>	Cortisol	Adult worms	↓ Reproduction, ↓ oviposition
<i>Taenia crassiceps</i>	Estradiol	Cysticerci	↑ Growth, ↑ reproduction
<i>Onchocerca volvulus</i>	Hydroxyecdysone	Microfilariae	↑ Metabolic activity
<i>Brugia malayi</i>	EGF	Microfilariae	↑ Growth, ↑ differentiation

EGF epidermal growth factor

The first indices of manipulation activity of *Toxoplasma* appeared in the 1960s–1970s of the twentieth century. Hutchison and his coworkers and successors published about 20 papers showing that congenital, acute, and even chronic toxoplasmoses have specific impacts on the behavior of infected mice. The infection was associated with hyperactivity in an open field (Hay et al. 1983, 1984b), increased voluntary wheel running (Hay et al. 1985), decreased ability to discriminate between familiar and novel stimuli (Hay et al. 1984a), impairment of motor performance and coordination (Hutchison et al. 1980a), and impairment of memory resulting in learning deficits (Piekarski et al. 1978; Witting 1979), for review see (Hutchison et al. 1980b; Skallová et al. 2006). In the 1990s, the manipulation activity of *Toxoplasma* started to be systematically studied by Joanne Webster in Oxford on a more suitable animal model, the rat (*Rattus norvegicus*). In contrast to short-lived and toxoplasmosis-sensitive mice, in this toxoplasmosis-tolerant animal, acute toxoplasmosis quickly proceeds into its latent stage (as usually occurs in humans) in which all clinical symptoms of disease disappear, but some specific behavioral symptoms of the parasite manipulation remain apparent for a long time. Infected rats express deficits in learning (Piekarski et al. 1978; Witting 1979), decreased neophobia and increased trappability (Webster et al. 1994), hyperactivity in a familiar environment (Webster 1994), and an increased exploration of a novel object (Berdoy et al. 1995). The most impressive product of manipulation activity described on this stage of research in rats, which was later confirmed also in mice and humans, is the so-called fatal attraction phenomenon, i.e., change their native, inborn fear of the odor of cats into an attraction to this odor (Berdoy et al. 2000). The infected mice and rats visit more often and stay longer in places containing the odor of cat urine. Conversely, they are not attracted by the odor of urine of other species (Vyas et al. 2007).

Some of the toxoplasmosis-associated behavioral changes weaken or even disappear with time from the infection and differ depending on strain of *Toxoplasma* and the species or strain of host. For example, the maximum reduction of mouse

activity and maximum impairment of reaction times of infected mice were observed at the peak of pathological symptoms and disappeared before 12 week postinfection (Hrdá et al. 2000). The fatal attraction phenomenon that was observed in mice 2 months after infection with two Type II strains of *Toxoplasma* (Prugniald and ME49) did not exist in ME49 after another 5 months; on the other hand, only this strain experienced impaired spatial working memory (Kannan et al. 2010). The *Toxoplasma* infection very often has different, frequently even contrasting, effect on behavior of males and females (Xiao et al. 2012). The Fatal attraction phenomenon was observed only in females of Balb/c mice, while a decrease in preference for novel food was observed only in male mice. Infected female mice expressed higher activity in open field test, while infected males expressed lower activity. A gene expression study revealed that *Toxoplasma* infection altered the expression of genes involved in the development of the forebrain, neurogenesis, and sensory and motor coordination in females, while in male mice, infection led mainly to modulation of genes associated with olfactory function (Xiao et al. 2012). Large *Toxoplasma* strain-specific differences were also observed in the concentration of various neurotransmitters in the brains of artificially infected animals, suggesting that Type I strains of *Toxoplasma* probably express the strongest manipulative activity (Abdoli 2013; Xiao et al. 2013). It is not clear yet which of the *Toxoplasma*-associated behavioral changes are products of manipulative activity of the parasite aimed to increase the probability of the transmission in latent phase of infection, which are the product of other manipulative activities of parasite, e.g., of the downregulation of the host immune functions, and which are just transient side effects of passed acute infection. The most convincing evidence for the manipulative nature of some of the observed toxoplasmosis-associated changes was obtained on other experimental model, namely, on humans (Flegr 2013b).

The study of *Toxoplasma* manipulation of human behavior started at the early 1990s of the past century. The first studies showed that personality profiles of subjects with latent toxoplasmosis

(about one third of humans worldwide) specifically differ from personality profile of *Toxoplasma*-free subjects (Flegr and Hrdý 1994). The intensity of changes in some personality factors increases with time since the infection or with decreases in anti-*Toxoplasma* antibodies. This suggests that these changes represent results of the cumulative effects of latent toxoplasmosis rather than transient after effects of passed acute infection. Some changes in personality are in the same direction in men and women, e.g., a decreased tendency for novelty seeking or decreased consciousness, while some are in the opposite direction in men and women, e.g., an increased Cattell's factor of protension in men and decreased in women and increased Cattell's factor of superego strength in women and decreased in men (Flegr 2010). The changes in personality profile are associated with corresponding changes in infected subjects' behavior. For example, *Toxoplasma*-infected men scored lower in tidiness of their clothes than uninfected men, whereas infected women scored higher than uninfected women (Lindová et al. 2006). In experimental games (dictator game and ultimatum game), the infected male students expressed less altruism, while infected women expressed more than their noninfected peers (Lindová et al. 2010). Latent toxoplasmosis may even be responsible for differences in some cultural traits between countries. For example, the prevalence of toxoplasmosis explains a significant portion of the variance in aggregate neuroticism among populations, in the "neurotic" cultural dimensions of sex roles and uncertainty avoidance (Lafferty 2006), and in the incidence of suicides (Lester 2010).

An analogous version of the fatal attraction phenomenon and the decreased psychomotor performance that were described originally in experimentally infected rodents was later observed in *Toxoplasma*-infected humans. In a double-blind experiment, infected men rated the smell of highly diluted cat urine (but not urine of other four animals) as more pleasant and infected women as less pleasant than *Toxoplasma*-free subjects (Flegr et al. 2011). Both infected men and women have impaired reaction times (Havlíček et al. 2001) and express many specific defects in cognitive

performance (Beste et al. 2014; Flegr et al. 2013; Stock et al. 2013), including in school achievements (Ferreira et al. 2013; Flegr et al. 2012b). Again, the impairment in reaction times increases with the time since infection when the age of subjects is statistically controlled. It is highly probable that observed changes in reaction times (and also decreased capacity of long-term concentration) are responsible for the observed about 2.6 times higher probability of traffic accidents and workplace accidents observed in *Toxoplasma*-infected subjects in about six independent studies in the past 10 years (Flegr et al. 2002; Kocazeybek et al. 2009; Yereli et al. 2006). The subjects with Rh-positive blood group are fully (heterozygotes) or at least partly (homozygotes) protected against deterioration of reaction times (Novotná et al. 2008), risk of traffic accidents (Flegr et al. 2009), and many other effects of latent toxoplasmosis as well as against other detrimental factors as smoking, aging, and fatigue, as demonstrated in subsequent studies (Flegr et al. 2012a). This byproduct of *Toxoplasma* manipulation activity research not only solved an old enigma surrounding the existence of the Rh polymorphism but could become important in many fields of human physiology and for clinical practices in the future.

The studies published mainly at the beginning of twenty-first century shed some light on the physiological mechanisms of *Toxoplasma* manipulation. *T. gondii* possesses two unique genes for key enzymes that catalyze the synthesis of the important neurotransmitter dopamine (Gaskell et al. 2009). These genes are expressed in *Toxoplasma* bradyzoites in tissue cysts in the brains of infected animals; a large amount of dopamine is produced there and is exported to the surrounding neural tissue (Prandovszky et al. 2011). The level of dopamine in the brain is known to negatively correlate with the personality trait of novelty seeking, one of the traits that is significantly lower in *Toxoplasma*-infected subjects. The increased level of dopamine or rather resulting imbalance in concentration of dopamine between different parts of the brain could also explain the tight connection between schizophrenia and toxoplasmosis, a phenomenon studied for more than 50 years (Willner 1997). It is known that the

imbalance in dopamine concentration plays a key proximal role in schizophrenia. Nearly all modern antipsychotic drugs either decrease the level of dopamine in the brain of schizophrenic patients or inhibit binding of this neurotransmitter to its receptors (Nikam and Awasthi 2008). Results of present studies suggest that toxoplasmosis plays an important role in the onset of schizophrenia in a significant portion of genetically predisposed patients. Moreover, the clinical picture of schizophrenia in *Toxoplasma*-infected patients differs from that of *Toxoplasma*-free patients. For example, the decrease in gray matter density in the brain occurs only in *Toxoplasma*-infected patients (Horacek et al. 2012), and the same is true for gender differences in the onset of schizophrenia – on average, a 3-year delay of the onset of the disease in women exists only in *Toxoplasma*-infected subjects (Holub et al. 2013). *Toxoplasma*-infected schizophrenia patients express more severe positive symptoms of the psychiatric disease (more frequent or intense hallucinations, delusions) than *Toxoplasma*-free subjects (Holub et al. 2013; Wang et al. 2006).

Men with latent toxoplasmosis have increased levels of free testosterone, while women have decreased levels (Flegr et al. 2008). It has been observed in a rodent model that *Toxoplasma* induces synthesis of these steroid hormones in the testes of infected males (Lim et al. 2013). Increased levels of testosterone could explain why *Toxoplasma*-infected men are on average 3 cm taller than their *Toxoplasma*-free peers, and their photos are also rated as more masculine and dominant by female raters (Flegr et al. 2005). It is possible that the increased level of testosterone results in higher competitiveness, which may also at least partly explain the higher risk of traffic accidents (however, this was observed also in female drivers) or the increased probability of birthing sons in women and in mice females with relatively recent *Toxoplasma* infection (Kaňková et al. 2007a, b). It is also not clear whether increased levels of testosterone are a symptom of manipulation activity by *Toxoplasma* aimed to increase its chance for successful transmission, or a part of its struggle with the host immune system (testosterone is known to have a

potent immunosuppressive activity), or whether it is just some nonadaptive side effect of the parasitic infection. In *Toxoplasma*-infected rats, however, the fatal attraction phenomenon (loss of the fear response to cat odor and its change into an attraction) can be observed only in intact, not castrated males (Lim et al. 2013). It can be also speculated that increased levels of testosterone in males, resulting in increased sexual activity, could result in increased efficiency of sexual transmission of *Toxoplasma*. Viable parasites were frequently observed in seminal fluid of infected males, and sexual transmission of toxoplasmosis from infected male to female during sexual intercourse was observed in many animal species. In humans, only indirect evidence for sexual transmission of toxoplasmosis exists (Flegr 2013a). It can possibly occur only in acute or post-acute phase of the infection, and therefore, the unprotected sex is possibly only a marginal risk factor of toxoplasmosis. However, it can play an extremely important role in acquiring the most devastating form of toxoplasmosis, congenital toxoplasmosis, i.e., in transmission of the parasite from mother in acute phase of the infection to a developing embryo. It is indicative that about two thirds of *Toxoplasma* infections in pregnant women cannot be explained by the known risk factors.

Clinical Relevance

Research of manipulation activity by *Toxoplasma* started as typical basic research in the field of evolutionary parasitology. Results obtained during the past 20 years, however, showed that this activity of the parasite could have an important effect on human well-being and that latent toxoplasmosis could have an even larger public health and economic impact than other forms of toxoplasmosis put together. For example, just the increased risk of traffic and workplace accidents could be together responsible for a similar number of deaths as malaria. Schizophrenia, which affects about 1 % humans, represents huge economic burden. The prevalence of toxoplasmosis also explains large part of between-countries differences in the incidence of other serious psychiatric

and nonpsychiatric diseases, including obsessive-compulsive disorder, epilepsy, suicides, and cardiovascular diseases (Flegr et al. 2014). At least some of the observed associations between these diseases and toxoplasmosis can be caused by manipulation activity of the parasite. Presently, no effective method of treatment of, or vaccination against, toxoplasmosis exists. However, the results of manipulation activity studies suggest that more effort should be focused not only on the prevention and treatment of *Toxoplasma* infection but also on the prevention of manipulative activity of this common parasite in the future.

► Pathology.

Host-Parasite Interface, Protozoa

The protozoan parasites developed a great variety of contacts to their hosts. The origin

of parasitism started surely from free-living stages, that entered the hollows of the host's body. Then more or less fixed attachments to inner surfaces occurred and finally penetration into cells took place. Once inside, the parasites became situated directly in the ► **cytoplasm** or were included into parasitophorous ► **vacuoles** (► **Host Cell Invasion**, ► **Coccidia**). From the latter several genera (e.g., *Toxoplasma*, ► *Sarcocystis*, ► *Frenkelia*, ► *Besnoitia*, ► *Cystoisospora*, *Hammondia*, *Neospora*, *Caryospora*) formed so-called tissue-cysts by ► **fortification** (= formation of a ► **primary cyst wall**) and development of species-specific protrusions of the original membrane of the parasitophorous membrane (► **Tissue Cyst**). The main features are summarized in Table 1.

Hotpops

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes demographically clustered populations of parasite infections (e.g., malaria, helminthiasis) which are mostly associated with travel history and occupation of infected persons.

The Noble Prize winner John Steinbeck sees similarities in his book *Of Mice and Men*. See ► [mites](#).

Hotspots

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This term describes geographically clustered populations of infected hosts that are proven to show comparatively higher levels of transmission of agents of diseases. These hotspots may occur at any level of transmission and thus are considered as fractal in nature of given biotopes.

Synonym of ► [Cyathostoma bronchialis](#).

House Fly

Musca domestica (► [Diptera](#)).

House Mouse Mite

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Trivial name for the mite species *Liponyssoides sanguineus*, which parasitizes mice and man.

Hovorkonema variegatum

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Human Granular Anaplasmosis (HGA)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,

Disease due to the tick transmitted bacterium
► [Anaplasma phagocytophilum](#).

Human Granular Ehrlichiosis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Old name for ► [human granular anaplasmosis](#), since the agent of disease had been renamed from *Ehrlichia phagocytophila* to ► [Anaplasma phagocytophilum](#).

Human Monocytic Ehrlichiosis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

See ► *Ehrlichia* species, tick transmitted bacterium inside monocytes.

Human Parasitic Diseases: Origins

Like other host species, humans harbour two kinds of parasites, from an evolutionary point of view. Some of them have been parasitic in the hominid lineage for a long time and have coevolved with our primate ancestors. Others are the result of lateral transfers (or “host-switchings”).

The classical example of parasites which are probably inherited from our primate ancestors is the nematode ► *Enterobius vermicularis*, simply because all other primates harbour species closely related to “our” parasite. This does not mean that lateral transfers of oxyurids did not occur between some species of primates but these transfers occurred inside the phylum.

The classical example of human parasites which are certainly the result of “true” lateral transfers is provided by schistosomes. There is no evidence that schistosomes evolved in primate hosts. On the contrary, a phylogeny based on DNA sequences showed that they have evolved in host phyla, rodents and ungulates. These studies led to the conclusion that the human parasite *Schistosoma mansoni*, the agent of intestinal schistosomiasis, is close to a rodent parasite, whereas the human parasite ► *S. haematobium*, the agent of urinary schistosomiasis, is related to ungulate parasites. It is probable that the schistosomes were acquired by hominids when they increased their contact with water sources in the African savannahs. The period of the host switching was tentatively suggested to be about

2 million years ago, on the basis of molecular comparisons. The origin of the genus *Schistosoma*, as deduced from molecular phylogeny, is in Asia.

Similarly, on the basis of molecular studies, it has been proposed that *Plasmodium falciparum* could be the result of a transfer from birds to humans, and also because the shape of the parasite (“*falciparum*”) seems better adapted to the shape of an avian red cell (oval) than to that of a primate red cell (circular).

Anderson and Jaenike have considered ► *Ascaris* from humans and pigs, which are morphologically closely related. Taking into account that domestication of pigs occurred between 7,000 and 20,000 years before the present time, the authors ask the question: did humans acquire the parasite from pigs or the contrary? Their study of the introns of several nuclear genes, of ribosomal DNA spacers, and of a part of mitochondrial DNA, suggests that the pigs are the ancestral hosts and that all the *Ascaris* of present-day humans originate from a unique event of lateral transfer from pigs, which could have occurred in Asia.

Many other parasites of mankind are probably the result of lateral transfers due to the invasion of new ecosystems and the acquisition of new behaviours by humans, which put them in contact with infective stages of parasites which had evolved in other phyla. The transfer is of course sometimes impossible. For instance, swimmers are frequently infested in lakes by ► cercariae of various bird schistosomes, but the disease is limited to a dermatitis (► “Swimmer’s Itch”) because the schistosomulae cannot mature into adult worms.

A lateral transfer is not necessarily followed by a ► speciation process. Humans may simply become a new species in the host-spectrum of the parasite. This has consequences on pathogenicity: when parasites have a wide host-spectrum, the optimal pathogenicity (► Virulence) cannot be selected in every host species. The pathology may remain either sub-optimal or over-optimal. This causes a permanent maladaptation of the parasite to certain of its hosts, sometimes to humans.

Humoral Immune Response (HIR)

HIR is concerned with B-lymphocyte cell products (i.e., formation of immunoglobulin (Ig) antibodies. The IgA, IgG, IgM, and IgE occur in different situations and are effective against parasites in different ways (e.g., neutralization of invading stages, agglutination, complement activation, facilitated opsonization, etc.).

Humoral Immunity

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This type of ► [humoral immune response](#) occurs in hosts after the following infectious diseases:

- Entamoebiasis
- Chagas disease
- Cryptosporidiasis
- Cysticercosis
- Leishmaniasis
- Lymphatic filariasis
- Malaria
- Naegleriasis
- Onchocerciasis
- Pneumocystosis
- Schistosomiasis
- Trypanosomiasis
- Visceral larval migrans

Hunterella

Genus of ichneumonid wasps, which parasitize as larvae in ticks. In some regions of West Africa *H. hookeri* kills about 90 % of the nymphs of *Rhipicephalus sanguineus*.

Hyalomma

Name

Greek: *hyalos* = glass, *omma* = eye.

General Information

Genus of hard tick species with two hyaline eyes (name); about 30 species are found in arid or semi-arid species in Africa, Asia, and southern Europe. Important as vector of ► [Theileria](#) stages is *H. anatolicum* *anatolicum* on ruminants and horses, while *H. marginatum* occurs on birds and *H. aegypticum* on turtles. The life cycle may be completed in less than 4 months, thus the infection risk is increased by this short period as well as by the fact that *Hyalomma* spp. may depone more than 10,000 eggs.

Hyaloplasm

Synonyms

Ectoplasm.

Hybomitra

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of so-called horse-flies (tabanids) related to ► [Tabanus](#), ► [Haematopota](#).

Hybridization

Formation of progeny between two different species (e.g., *Schistosoma mansoni* and ► *S. japonicum* or ► *Fasciola hepatica* and *F. gigantea*).

Hydatid Disease

Synonyms

Hydatidosis, cystic echinococcosis.

Hydatids

Large (up to 20 cm in diameter), fluid-filled cysts formed by *Echinococcus granulosus* inside intermediate hosts (e.g., sheep, humans). The aqueous fluid contains thousands of brood capsules and protoscolices that are infectious to the final hosts (e.g., dogs, foxes).

Hydatigera taeniaeformis

Synonym of *Taenia taeniaeformis*, ► **cestodes**; tapeworm of cats and other felids reaching a length of up to 60 cm; intermediate hosts are rodents harbouring so-called strobilocercus larvae.

Hydrogenosomes

The ► **trichomonads**, which are anaerobic, have ► **microbodies** called hydrogenosomes. They are limited by mostly 2 closely attached membranes surrounding a granular matrix (► **Trichomonadida**, Fig. 1c, e). The enzyme system of these bodies differs from that of ► **mitochondria**, as they metabolize pyruvate from ► **glycolysis** into acetate, CO₂ and H₂. In ciliates, similar hydrogenosomes with double membranes

are present, in addition to regular ► **mitochondria** (► **Energy Metabolism**).

Hydrogenosomes: Origin

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Recent hydrogenosomes have apparently different origins and have evolved several times at different places. As is shown in molecular biological analysis and in phylogenetic reconstructions of rRNA data, they represent strongly reduced anaerobic stages like mitochondria (without inner invaginations). In general DNA is absent in hydrogenosomes and their essential proteins are encoded inside the nucleus of the cell. As mitochondria hydrogenosomes have the same evolutionary origin since that in both cases, a free-living proteobacterium was engulfed by a cell and stayed there as endosymbiont. They possess therefore like recent mitochondria two limiting membranes consisting of phospho- and glycolipids. In contrast to mitochondria, hydrogenosomes obtain their energy by phosphorylation by the help of substrate chains, while mitochondria use an electron transportation chain. As well as in contrast to mitochondria, most hydrogenosomes have no own genome, and thus all their proteins are encoded by the cell nucleus and are imported into the hydrogenosomes by the help of several membrane complexes.

Hydropene

Chemical Class

Juvenile hormone agonist (juvenile hormone analogue).

Mode of Action

Insect growth regulator (IGR, juvenile hormone mimics). ► [Ectoparasiticides: Inhibitors of Arthropod Development](#).

Hydrotaea

Genus of the fly family Muscidae; important species are *H. irritans* (5.5–7 mm long) of cattle being called head and udder fly. The larvae live in the feces, highest activity is in July and August. This fly is involved in the disease described as summer mastitis. On horses *H. albipuncta* occurs in addition to *H. irritans*. Ectoparasiticides.

Hygiene

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term comes from Greek, *hygieia*, the goddess of health, which was depicted as a young woman with a snake around her arm or as a woman who offered a vessel with water to a snake. Snakes were considered as holy animals of the Earth gods, transmitting the health and power of the goddess if humans sleep inside her temple. In the eighteenth century, hygiene became a special field of human and veterinary medicine that provides information on how transmission of viruses, bacteria, fungi, and parasites can be avoided. See works of famous people such as Ignaz Semmelweis (1818–1865), the father of obligatory handwashing, or ► [Koch](#),

[Robert \(1843–1910\)](#) or ► [Max von Pettenkofer \(1818–1901\)](#).

Hygiene Hypothesis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This hypothesis, which is supported when looking at many parasitic infections, is based on the finding that parasites may influence intensively the immune system of their host by stimulation of its activity. Thus it was concluded that the diseases of our modern times such as Crohn syndrome, allergies, autoimmunity effects, metabolic syndrome, etc. are consequences of the strongly and constantly diminished exposure to infectious agents of diseases in our days in Europe and USA. In consequence, it becomes intelligible that artificial exposure of humans to pathogens (e.g., infections of humans with *Trichuris suis*) reduces symptoms due to autoimmune diseases such as Crohn syndrome or ulceritis.

Hymenelopsis nana

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *hymen* = thin portion of skin; *lepis* = scale. Latin: *nanus* = dwarf. English: dwarf tapeworm.

Geographic Distribution/Epidemiology

Worldwide, especially in the subtropics and tropics, about 80 millions of humans are infected. It is probably the most common tapeworm of humans (especially of children).

Morphology/Life Cycle

H. nana parasitizes in humans, mice, and rats and reaches mostly only a length of 5 cm and a width of 1–2 mm (Figs. 1 and 2). The scolex has a diameter of 0.3 mm, is provided with four suckers,

Hymenolepis nana, Fig. 1 Life cycle of *Hymenolepis* species. (a) Species and final hosts (see ► [Eucestoda](#), Table 1): ► [Rodentolepis](#) (*Vampirolepis*, *Hymenolepis* *nana* (*fraterna*) of mice and humans, 4–6 cm long and 1 mm broad, scolex with 24–27 rostellar hooks; ► *Hymenolepis diminuta* of rats, mice, dogs, and humans, up to 6 cm long and 3–5 mm broad, no rostellar hooks; *Echinolepis* (*Hymenolepis*) *carioca* of chicken and birds. Strobilia up to 8 cm long and 3–5 mm broad, scolex has no rostellar hooks. The sexually mature proglottids are characterized by three spherical testes (TE); there is the distinct border wall between the proglottids (dotted lines). (b) Intermediate hosts (► [Eucestoda](#), Table 1). 1–4 Eggs containing the ► [oncosphaera](#) larva (1 *H. nana*, 40–60 × 30–50 µm; 2 *H. diminuta*, 60–80 × 70 µm) are infectious to various insects (larvae adults) as intermediate

hosts (3, 4). 5 Inside the body cavity of these hosts a second larva (► [cysticercoid](#)) is formed, which grows to be a mature tapeworm when the intermediate host is swallowed by the final host. In *H. nana*, the intermediate host is optional when eaten by a man or a rodent, the egg (1) hatches in the duodenum, releasing the ► [oncosphaera](#), which penetrates the mucosa. Here it develops directly into a cysticercoid (5). In about 6 days the ► [cysticercoid](#) emerges into the lumen of the small intestine, where it attaches and grows to be a mature worm. EM ► [embryophore](#) (layer surrounding the oncosphaera), EX excretion system (longitudinal), ES eggshell, GP genital pores, HK hooks of oncosphaera, ON oncosphaera, OV ovary (► [germarium](#)), SU sucker, TE ► [testis](#), VD vas deferens, VG vagina with enlarged seminal vesicle, VI ► [vitellarium](#)

and bears a protrudable spherical rostellum, which is armed by 20–24 hooks (Fig. 2), which are tiny, reaching a length of 140–180 μm . Mature proglottids are often already destroyed in the intestine of their hosts, so that the characteristic eggs (40–60 $\mu\text{m} \times 30$ –50 μm) are mostly found in the feces (Fig. 2). The further life cycle is diagrammatically depicted in Fig. 1.

Symptoms of Disease (Vampirolepiasis, Hymenolepiasis)

Immunologically healthy persons develop a cell-dependent immune reaction, which suppresses the endogeneous autoinfection and thus helps to avoid the increasing inflammation of the mucosa that hits children and immunosuppressed (immunocompromised) persons severely. Therefore immunocompetent persons show only low-grade symptoms such as abdominal pain, slight diarrhea, or weakness. On the other side immunocompromised persons, children or adults,

with a huge number of worms show much more severe symptoms: abdominal cramps, bloody diarrhea, loss of weight, blood eosinophilia, severe dizziness (Figs. 3 and 4).

Diagnosis

The most effective method is microscopical determination of the eggs after use of concentration methods such as ► [S.A.F.C.](#), ► [M.I.F.C.](#), and ► [flotation](#). Blood shows often a low-grade eosinophilia.

***Hymenolepis nana*, Fig. 3** Scanning electron micrograph of an adult *Hymenolepis* worm

***Hymenolepis nana*, Fig. 2** Scanning electron micrograph of the scolex and neck region of an adult *Hymenolepis nana* worm

***Hymenolepis nana*, Fig. 4** Macrophoto of the cysticercoid of *H. nana*

Infection

There are several possibilities:

- Oral uptake of cysticercoid larvae within insects of portions of them (insects are eaten in several countries)
- Oral uptake of *H. nana* eggs in fecally contaminated food (probably main pathway of infection)
- By endogenous autoinfection, if larvae from eggs already hatch in the intestine of patients (e.g., in cases of delayed defecations)

Prophylaxis

Avoid contact to human feces and oral contact to insects.

Incubation Period

1–4 weeks; however, symptoms may lack or remain nonspecific.

Prepatent Period

2–4 weeks.

Patency

2 months; reinfections are possible.

Therapy

Drug of choice is praziquantel (1×25 mg/kg bodyweight), since it acts against adults and against cysticercoid larvae. Niclosamide is also effective; however, it must be given for 7 days (2 g) and a repetition after 3 weeks is recommended.

Hymenolepiasis

General Information

The cestode *Hymenolepis nana* (syn. ► *Rodentolepis nana*) is primarily a parasite of rodents, but is also frequently found in man where it is autoreproductive, but in general not very pathogenic. Figure 1 shows the presence of man-man, rodent-rodent, man-rodent, and rodent-man cycles.

Targets for Intervention

Possible targets are the rodent reservoir, the human cases, transmission both from and to man, and the environment where infective material may be encountered (Fig. 1). It is evident that one approach on its own will probably do very little to improve the situation.

Main clinical symptoms: Malnutrition, ► *diarrhoea*, ► *abdominal pain*.

Incubation period: 1–4 weeks.

Hymenolepiasis,

Fig. 1 Targets and approaches for the control of hymenolepiasis

Hymenolepiasis, Fig. 2 LM of an egg of *Hymenolepis nana*

Hymenolepiasis, Fig. 3 LM of an egg of *Hymenolepis diminuta*

Prepatent period: 2 months.

Patent period: 2–4 weeks.

Diagnosis: Microscopic diagnosis of eggs in fecal samples (Figs. 2 and 3).

Prophylaxis: Avoid contact with rodent and human feces.

Therapy: Treatment with praziquantel, ► [Cestodocidal Drugs](#).

Classification

Hymenolepididae

Family of ► [Eucestoda](#).

Name

Greek: *hymen* = fine membrane, *lepis* = scale.

Hymenolepididae, Fig. 1 Life cycle of ► [tapeworms](#) of the family Hymenolepididae. (a) Species and final hosts (others see ► [Eucestoda](#)/Table 1): ► [Rodentolepis](#) (*Vampirolepis*, *Hymenolepis*) *nana* (*fraterna*) of mice and humans, 4–6 cm long and 1 mm broad, scolex with 24–27 rostellar hooks; ► *Hymenolepis diminuta* of rats, mice, dog, and humans, up to 6 cm long and 3.5 mm broad, no rostellar hooks; *Echinolepis* (*Hymenolepis*) *carioca* of chickens and birds. ► *Strobila* up to 8 cm long and 3–5 mm broad, scolex has no rostellar hooks. The sexually mature proglottids are characterized by 3 spherical testes (TE); there is no distinct border wall between the proglottids (dotted lines). (b) Intermediate hosts (► [Eucestoda](#)/Table 1). 1–4 Eggs containing the ► [oncosphaera](#) larva (1 *H. nana*, 40–60 × 30–50 µm; 2 *H. diminuta*, 60–80 × 70 µm) are infectious to various insects (larvae,

adults) as intermediate hosts (3, 4). 5 Inside the body cavity of these hosts a second larva (► [Cysticercoid](#)) is formed, which grows to be a mature tapeworm when the intermediate host is swallowed by the final host. In *H. nana* the intermediate host is optional; when eaten by a man or a rodent, the egg (1) hatches in the duodenum, releasing the ► [oncosphaera](#), which penetrates the mucosa. Here it develops directly into a cysticercoid (5). In about 6 days the ► [cysticercoid](#) emerges into the lumen of the small intestine, where it attaches and grows to be a mature worm. EM ► [embryophore](#) (layer surrounding the oncosphaera), EX excretion system (longitudinal), ES egg-shell, GP genital pores, HK hooks of oncosphaera, ON oncosphaera, OV ovary (► [Germarium](#)), SU sucker, TE ► [testis](#), VD vas deferens, VG vagina with enlarged seminal vesicle, VI ► [vitellarium](#)

H

Hymenolepis diminuta

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

From Greek: *hymen* = thin membrane, *lepis* = cover. Cestodes, Hymenolepidae (Fig. 1).

***Hymenolepis gracilis* (syn. *Sobolevicanthus gracilis*)**

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This tapeworm occurs in the small intestine of many water birds and chickens in Europe, North

America, Africa, and Asia, reaches a length of 40 cm and a width of 3 mm, possesses eight rostellar hooks, and uses small water crustaceans as intermediate host. Its prepatent period is 9–11 days.

***Hymenolepis lanceolata* (syn. *Drepanitotaenia*)**

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This tapeworm occurs in the intestine of geese, chickens, and ducks, has a length of up to 25 cm, a rostellum with eight hooks, and uses small water crustaceans as intermediate hosts. Its prepatent period is 15–25 days.

Hymenolepis microstoma

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

► [Cestodes](#), ► [Hymenolepiasis](#) (Fig. 1).

***Hymenolepis microstoma*, Fig. 1** Scanning electron micrograph of the apical aspect of the scolex

Hymenolepis minutissima

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Tapeworm of chickens, which uses beetles (► [Alphitobius diaperinus](#)) as intermediate hosts.

Hymenoptera

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Greek: *hymen* = god of wedding, fine skin; *pteron* = wing.

The name describes an order of the Hexapoda (six feet animals = *Insecta*) which includes, e.g., wasps, bees, and ► [Ichneumonidae](#). Some of the latter live as ► [parasitoids](#).

Hyostrogylus

Name

Greek: *hyo* = belonging to, *strongylos* = rounded.

Classification

Genus of the nematode family Trichostrongylidae.

General Information

This so-called red-stomach-worm of pigs reaches as female about 1.2 cm in length, the males are only 0.7 mm long. The worms suck blood in the stomach and after copulation the 70–85 × 40 mm sized eggs appear in the faeces. After some days the larva 1 hatches from the egg and develops into larva 2, which survives often for 1 year in the food. After oral uptake the larva 3 develops within 3 weeks (including 2 moults) into the adult stage.

Disease

► [Alimentary System Diseases, Swine](#).

Hyperapolytic

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *hyper* = more, higher; *apo* = away; *lysis* = separation, dissolving. This term describes the special way of how proglottids of tapeworms are separated from the strobila. In this case single proglottids are separated at the end of the “tape” (strobila) immediately after fertilization.

Hypergammaglobulinemia

Symptom of disease in cystic ► [echinococcosis](#) and in ► [malaria](#) being characterized by an enormous amount of gamma-globulines in the blood.

Hyperinfections

Name

Greek: *hyper* = over, Latin: *inficere* = infect.

Infections with enormous amounts of parasites, which then disseminate also in other than the normal organs, e.g., in ► [Strongyloides stercoralis](#), *Capillaria philippiensis*. This often is the case, when ► [autoinfection](#) is possible.

Hyperkeratosis

Symptom of diseases due to ► [Onchocerca volvulus](#). The microfilariae in the skin introduce an immune reaction described also as “paper skin.”

Hypermastigida

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Classification

Order of ► [Mastigophora](#).

General Information

Members of the Hypermastigida (Fig. 1), like the ► [Oxymonadida](#), inhabit the intestine of wood-feeding insects and are involved in the digestion of cellulose; however, the question of whether they produce the necessary enzymes themselves or whether they are obtained from endosymbiotic bacteria has not yet been answered. Others are found in the intestine of cockroaches (e.g., ► [Barbulanympha](#); see Gametes). This group is characterized by the occurrence of many repeated sets of four-apical ► [flagella](#), which are arranged

Hypermastigida, Fig. 1 LM of a specimen of the order Hypermastigida from the intestine of cockroaches

in a trichomonadid-like basal pattern, thus giving them the appearance of a wild tuft. Reproduction occurs by longitudinal division, while sexual processes are unknown. During this process, the flagella become resorbed except for a set of four; their duplication initiates the cell division and the final formation of other flagella sets. In some species, transmission occurs by oral uptake of fecally passed cysts.

Hypermastigina

Order of flagellates with numerous apical ► [flagella](#), ► [Barbulanympha](#).

Hyperparasitism

A second type of parasite is hidden inside a parasite and thus is also fed indirectly by the host.

Hyperplasia

From Greek: *hyper* = over and above, *plasso* = formation. Some parasites introduce an enlargement of organs. ► [Pathology](#).

Hypertrophy

Enlargement of cells due to parasitism, e.g., ► [Theileria](#) schizonts, *Trichinella*.

Hypnozoites

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The name of these stages comes from Greek: *hypnos* = sleep; *zoon* = animal. Hereby, sporozoites of the genus ► [Cystoisospora](#) are described, which stay in parasitophorous vacuoles/tissue cysts of several hosts without further development until a carnivorous final host ingests them. In this final host, the typical schizogony, gamogony, and sporogony are initiated by these hypnozoites, which are also called dormozoites = sleeping cells by Jack Frenkel (USA).

Further Reading

Markus MB (2011) They hypnozoite concept, with particular reference on malaria. *Parasitol Res* 108:247–252
 Richter J et al. (2010) What is the evidence for the existence of Plasmodium ovale hypnozoites? *Parasitol Res* 107: 1285–1290

Hypoalbuminemia

Clinical symptom in animals due to parasitic infections (Alimentary System Diseases, ► [Clinical Pathology](#), [Animals](#)).

Hypobiosis

Delayed ongoing of development (► [Trichostrongylidae/Life Cycle](#), ► [Lung-worms](#), ► [Nematodes](#)).

Hypodectes

Genus of mites in the nests of birds (e.g., *H. propus* of doves).

Hypodectes propus

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Mite species, which develops a 1.5 mm long ► [hypopus](#) stage (deutonymph) inside the subepidermal layer of doves.

Hypoderaeum conoideum

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trematode species. The adults of this species parasitize in the intestine of ducks and geese. Humans become infected, if they ingest raw water snails. The life cycle runs like that of *Echinostoma* species. The typical anterior collar is provided with 47–53 spikes and the eggs measure $100 \times 65 \mu\text{m}$.

Hypoderma

From Greek: *hypo* = below, *derma* = skin.
 ► [Diptera](#).

Hypoderma bovis

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Warble fly

Hypoderma bovis, Fig. 1 Life cycle of *Hypoderma bovis* (warble fly). 1, 2 Adult females lay several hundred eggs which are singly deposited and become attached to the host's hair (2.1) by an attachment organ. The first-stage larva hatches from the egg in about 4 days, crawls down the hair, and penetrates the skin. 3 The exact route taken by migrating larvae in the host is not known, but after several months, they reach the final site, the epidural fat of the spinal canal (3.1). 4–6 At the beginning of the year, the LI leave the spinal canal and move to their final site on the back; this is an area of 25 cm on either side of the midline from shoulder to tail and is where the cysts (=warbles) are formed from March to July. The LI (3.1) measures about 10 mm in length just after arrival; it molts into the second-

stage larva soon after reaching the skin and cuts a hole (HO) in it through which it respire by means of paired terminal ► [spiracles](#). After molt, the third larval ► [instar](#) appears and then develops into the 30-mm-long prepupa (6). After several weeks, the yellowish-brown prepupa forces its way through the skin's opening, drops to the ground, and moves, actively seeking shelter. 7 The pupal stage needs 3–10 weeks depending upon external conditions (*H. lineatum* needs 4 weeks or less). Adults of *Hypoderma bovis* appear from June to mid-September, are unable to feed, and live for only 3–5 days; they emerge early in the day and mate within 1 h. CY cyst, or warble, H hair, HK larval mouth hooks, HO hole in the skin, OP opening (for emergence) in the pupal ► [cocoon](#)

Classification

Species of ► [Diptera](#).

Hypoderma diana

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *hypo* = below; *derma* = skin. Latin: Diana = goddess of hunting.

This warble fly usually infests the skin of animals of the groups of red deer, fallow deer, roe deer, and mouflon. Occasionally also infestations of sheep, donkeys, horses, and even humans have been reported. In all these cases, mostly more than larva-containing nodules had been diagnosed per infested animal thus

indicating that infection pressure and damages were high.

Hypodontus macropi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Hypodontus macropi is a nematode (Strongyloidea) parasitizing macropodid marsupials in Australia.

Further Reading

Chilton NB et al (2012) Genetic variation within the *Hypodontus macropi* (Nematoda, Strongyloidea) complex from macropodid marsupials. Electrophoresis 33:3544–3554

following stage with respect to morphology and behavior. This so-called hypopus stage has no functional mouthparts and is a facultative developmental route which may be present in the life cycle of a mite generation. This special phenotype of a deutonymph can survive bad environmental influences much better than the normal form. The hypopodes are able to attach themselves to animals by ventral suckers or claspers and are thus transported to new environments or hosts (► [Phoresis](#)). In the genus *Glycyphagus* inert hypopodes occur, which remain within the exuvia of the protonymphs; they are not provided with organs to fix themselves and thus can be moved by air currents. In certain members of the family Glycyphagidae (e.g., *Rodentopus sciuri*) the hypopus also lacks organs for attachment. The hypopus forms of these ► [mites](#) are found in the subepidermal tissues of various animals. ► [Mites/Ontogeny](#).

Hypoglycemia

A frequently encountered complication in *Plasmodium falciparum* ► [malaria](#), which is apparently based on increased use of glucose and impaired glucose production due to inhibition of gluconeogenesis.

Hypopus

In members of the Acaridida the ► [deutonymph](#) is completely different from the preceding and the

Hypopygidium

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Hypopygidium is the male sexual organ of flies of the Calyptratae group.

Hypostome

Ventral part of the gnathosoma of ► [ticks](#) (► [Ticks/Alimentary System](#)).

Hypoxia

From Greek: *hypo* = below, *oxys* = oxygen. Lack of oxygen. Endoparasites have to develop systems to survive this lack Anaerobiosis.

Hyptiasmus arcuatus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trematode species that lives in the nose, infraorbital caverns, and the trachea of geese, ducks, and other water birds in Europe, Asia, and America. Their size ranges: 8–20 × 2–5 mm.

Hysterosoma

From Greek: *hystera* = uterus, *soma* = body. This term describes the 3rd and the 4th, legless abdominal region of ► [Acari](#).

Hysterothylacium aduncum

Nematode species in the mesenteries and intestine of flat fish of Baltic sea.

Hystrichis tricolor

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Species belonging to the family Dioctophymatoidea (► [Dioctophyme renale](#)). *Hystrichis tricolor* appears three-colored, reaches a size of 40 mm in females and 25 mm in males, and lives in the digestive stomach of wild and domestic birds in Europe. Intermediate hosts are earthworms.

Ichneumonidae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The name comes from Greek: *ichneuein* = to hunt out or hunt up.

The family of the so-called parasitic wasps (e.g., *Ichneumon nigrarius*) represents the biggest group among the Hymenoptera and among the so-called ► [parasitoids](#), which also include species from other insect groups. The European wood wasp *Rhyssa persuasoria* reaches a body length of up to 5 cm and has a similarly sized ovipositor, by the help of which it injects its eggs into larvae of butterflies (Lepidoptera), beetles (Coleoptera), or even eggs of spiders (Arachnida). Since these ichneumonids mostly kill their hosts, they are called ► [parasitoids](#), since the interest of “true parasites” must be to keep alive their hosts, since they have no more a free-living stage.

Ichneumonids have in nature an enormous impact on the control of pests reaching infestation rates of up to 80 % among their host species. Some of these species are now bred in industrial cultures and were used – especially in stores or in greenhouses – for pest control (e.g., against moths). Even Charles Darwin mentioned the ichneumonids in a letter to the American naturalist Asa Gray, when he expressed his doubts on the existence of a “good God” that should have created willingly also creatures that are cruel to others saying:

I own cannot see as plainly as others do, and as I should wish to do, evidence of design and beneficence on all side of us. There seems to me too much

misery in the world. I cannot persuade myself that a beneficent and omnipotent God would have designedly created the Ichneumonidae with the express intention of their feeding within the living bodies of caterpillars, or that a cat should play with mice.

Ichthyobodo necator

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Costia necatrix

Classification

Phylum Euglenozoa, Classis Trypanosomatidae, Order Bodonida

Morphology

The spherical, free-swimming ($10\text{--}20 \times 6\text{--}10 \mu\text{m}$) swarmer has two flagella (9 and $18 \mu\text{m}$ long) and a long typical mitochondrial kinetoplast (Fig. 1). The reproduction occurs by binary fission. The free-swimming stages become attached to the surface of a fish and then appear pear-shaped (Fig. 2) and develop a chitinous layer as outer cover.

Life Cycle

After feeding, the fixed trophozoites (Fig. 2) detach from the skin, sink to the ground, close the feeding opening, and thus become a cyst, within which 256 so-called dinospores (or swarmers) are formed, which must find a host within 24 h.

***Ichthyobodo necator*, Fig. 1** Diagrammatic representation (DR) of the swarmer of *Ichthyobodo necator*

***Ichthyobodo necator*, Fig. 2** DR of the skin-attached trophozoite of *Ichthyobodo necator*

Therapy

FlagelloTM (Sera) (nitroimidazoles).

Mehlhorn B et al (1992) Health for ornamental fish.
Springer, Heidelberg

Ichthyophonus, Fig. 1 Macroscopic presentation of a so-called discus fish parasitized by *Ichthyophonus* stages (white fields and filament-like strands at the lower side). In addition the tail is damaged by bites of skin worms

Ichthyonema

Name

Greek: *ichthys* = fish, *nema* = filament.

Synonyms

Philometra spp. of fish nematodes, which reach as females a length of 5 cm and a diameter of 1 mm (males 2–3 mm long). They parasitize inside blood vessels, body cavity, and in/on the gills. *Cyclops*-crustaceans are apparently the intermediate hosts.

Ichthyophonus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This genus includes fungi that induce skin lesions in fish which are very similar to effects of animal parasites (Figs. 1 and 2).

Ichthyophonus, Fig. 2 Diagrammatic representation of hyphen formation (1) and formation of endospores of *Ichthyophonus*. Each spore grows up into a multinucleated, thick-walled stage (1) as soon as it gets into contact with another fish or another region of the skin of the same fish

Ichthyophthiriasis

Disease of free freshwater and ornamental fish due to an infection with the holotrich ciliate ► *Ichthyophthirius multifiliis*, which lives between the epidermis and the corium. Infection can be diagnosed by the occurrence of white dots on the skin (= other name for the disease: white-dots disease). Fish try to get rid of the apparently itching parasites by scrubbing at stones etc.; their fins are kept compressed. If gills are highly infected, fish show apathy, do not feed, are seen in a lateral upside-down position, do not show escape-reflexes and may die due to inflammation of the skin lesions within 4–5 days.

Therapy

ProtazolTM (Sera/Alpha-Biocare).

Ichthyophthirius multifiliis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *ichthys* = Fisch, *phtheiros* = louse;
Latin: *multus* = much, *filia* = daughter.

***Ichthyophthirius multifiliis*, Fig. 1** Life cycle of *Ichthyophthirius multifiliis* parasitizing many species of freshwater fish. 1 ► **Swarmer** penetrates the skin of a fish and becomes encysted (EN) by host tissues. 2 The encysted ► **swarmer** grows to be a trophozoite, reaching a diameter of up to 1 mm; the skin then presents with a large grayish pustule at these places. 3 Upon rupture of the pustules, the ► **trophozoites**, which have numerous contractile ► **vacuoles**, are liberated and swim about feebly. Upon coming to rest on the bottom of the pond, the ► **trophozoite** secretes a thick-walled gelatinous cyst wall about itself. 4–8 Within

an hour of ► **encystation**, the mother trophozoite starts reproduction by simple transverse division, this being repeated until up to 1,024 30–50 µm-long, pear-shaped swarmer (with a single contractile vacuole) are formed. 9 After rupture of the cyst, the liberated swarmer attaches to the skin of fish within 1 day (unattached ones die during the second day). CI ► **cilia**, CV contractile vacuole, CW cyst wall of cysts on the bottom of the pond, CWS cyst wall in skin, CY ► **cytostome**, EN encysting swarmer, LC long terminal cilium, MA ► **macronucleus**, MI ► **micronucleus**, OP opening rupture of CW, SW swarmer

IMC

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This is the abbreviation for the **inner membrane complex** of the so-called ► *pellicle* of ► *apicomplexan* asexual motile stages such as sporozoites, ► *merozoites*, ► *tachyzoites*, ► *bradyzoites*, and ► *cystozoites*, which consists

of two adjacent membranes (formed by flattened ER lacunes) and attached species-specific numbers of ► *subpellicular microtubules*. The IMC of gametocytes and that of all types of zoites contains several distinct proteins: alveolins, multitransmembrane proteins, ► *glideosome*-associated proteins 45 and 50, myosin A, and myosin-A-tail interacting protein.

Imidacloprid

Norbert Mencke¹ and Heinz Mehlhorn²
¹Animal Health Division, Bayer HealthCare AG, Leverkusen, Germany
²Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Ectozide developed to protect dogs and cats against ticks, fleas, etc. In combination with flumethrin (Seresto[®], Foresto[®]), it protects for 7–8 months against ixodid ticks and fleas. In combination with permethrin (Advantix[®]), it protects for 4 weeks against ixodid ticks and fleas. In combination with moxidectin (Advocate[®]), demodicosis and scabiosis are avoided. Phlebotomids are repelled for 2–3 weeks by a combination of imidacloprid and permethrin (Advantix[®]).

Immune Complex

Synonyms

Antibody–Antigen Interaction.

General Information

The formation of immune complexes with subsequent clearance is a physiological process during the acute phase of an immune reaction. When antibody-antigen aggregates develop in rising

quantities they become detectable in the peripheral blood as so-called circulating immune complexes (► [CIC](#)). The formation of CIC is a common event during chronic parasitic infection like schistosomiasis, filariasis, leishmaniasis, trypanosomiasis, toxoplasmosis, and quartan ► [malaria](#). Only the deposition of immune complexes may cause severe pathological changes in the host.

During parasitic infection various circulating antigens appear at different developmental stages. Due to a selective immune response only few of them are complexed by antibodies. The antibody–antigen interaction may lead to structural changes in the antigen. The clearance of immune complexes depends on the structure of the antigen and the quality (affinity) and quantity of the antibody.

Immune complexes are able to bind complement compounds and to activate the cellular immune response via Fc-receptors. Resulting pathological changes are either membrane proliferative glomerulonephritis or, when the antigen is tissue bound, an ► [Arthur's Phenomenon](#).

CICs are a common phenomenon in the sera of ► [Wuchereria bancrofti](#)-infected patients. Renal abnormalities like chronic progressive glomerulonephritis are reported for patients with malaria (*Plasmodium malariae*) and ► [Bancroftian filariasis](#). Also, a chronic *Leishmania infantum*-infection in dogs may cause glomerulonephritis.

Immune Evasion

Mechanisms developed by parasites to survive the attack of the host immune system (► [Immune Responses](#)).

Immune Responses

A general feature of many parasitic infections by ► [protozoa](#) or helminths is their chronicity and

several reasons contribute to this, e.g., weak ► [innate immunity](#) and the capacity of parasites to withstand or to evade destruction by specific immune responses of the vertebrate host. General aspects of the various host immune responses are described in the following. Peculiarities of the immunological response to specific parasites are described in detail under the headwords of the respective diseases.

Innate Immunity

The skin and the linings of the respiratory, gastrointestinal, and urogenital tract present formidable physical and chemical barriers to infective organisms and represent a first line of defense. These barriers provide a ► [natural resistance](#), also called innate immunity, to infection, but they are not perfect. Protozoan and helminthic parasites, have evolved in such a way that they either are able to penetrate the body's barriers directly or are transmitted by insect bites.

In the body the alternative pathway of complement activation provides a first line of defense against many parasites. The complement component C3 is cleaved spontaneously in plasma to produce C3b; once bound to the parasite surface and stabilized to form a C3 convertase, activation of the terminal complement components C5–C9 takes place, and the parasites are lysed by the major attack complex MAC. A second line of defense is provided by macrophages and neutrophilic leukocytes, which play a major role in all stages of host defense. These cells by means of their CR3-receptors are able to recognize microbial substances and thus ingest the parasites. In addition, Toll-like receptors (TLRs) have been defined as important transmembrane receptors that confer a certain degree of specificity to the cells of innate immune system. TLRs have been implicated in recognition of every known category of pathogen that causes infectious disease. TLRs can recognize minute concentrations of microbial components and orchestrate an early defense, largely dependent on the MyD88-dependent activation of NF-κB, which will trigger microbiostatic/microbicidal effector mechanisms

and lead to the production of proinflammatory cytokines thereby also shaping the adaptive immune response. The importance of the TLR-mediated signaling pathways in the host resistance and pathogenesis during parasitic diseases has been demonstrated by experimental infections of MyD88-deficient mice with various protozoan parasites and helminths. The identification of a single TLR involved in the *in vivo* host responses to protozoan parasites has been a more difficult task, because protozoan parasites might be recognized by more than one TLR. Nevertheless, a number of distinct molecules derived from protozoan parasites have been shown to activate cells from the innate immune system via TLRs, e.g., glycosylphosphatidylinositol anchors from parasite surface proteins are recognized by TLR2, nucleic acids by TLR3 and TLR9, and a profiling-like protein of *Toxoplasma gondii* by TLR11, respectively. As a result of the TLR-stimulation and the parasite uptake, the secretion of cytokines by phagocytes is initiated which include interleukin-1 (IL-1), IL-6, IL-8, IL-12, and tumor necrosis factor (TNF). These factors recruit more phagocytes to the site of the infection and an increase in circulating neutrophils. Phagocytes also release other proteins with significant local effects, such as oxygen radicals, peroxides, ► [nitric oxide](#), prostaglandines, leukotriens, complement components, etc. Infection of cells with viruses, but also with parasites induced the production of interferon (IFN)- α and - β . These interferons contribute to the inhibition of natural killer cells (NK-cells), cells which are known to function in the initial phase of infection with intracellular pathogens, including parasites such as ► [Leishmania](#). Activated NK-cells secrete large amounts of IFN- γ . This IFN- γ is critical for the control of some parasitic infection before T cells have been triggered to liberate this cytokine. A further effect of IFN- α and - β is to augment the expression of MHC class I molecules, which favors the ability of host cells to present parasite antigenic peptides to CD8⁺ cells (see below). Once parasites have survived the innate immune response, the ► [acquired immunity](#) comes into effect.

Acquired Immunity

Acquired immunity is mediated by the humoral and cellular immune system, in which the B-lymphocytes are mediators of the humoral responses. Upon direct recognition of the parasites, i.e., antigen, they produce antibodies of different isotypes, that are specific for the antigen. A remarkable difference between bone marrow-derived B and thymus-derived T cells is the inability of T cells to recognize antigens directly as B cells do. T cells, on the other hand, need adequate presentation of antigens mostly by major histocompatibility complex (MHC) molecules expressed on antigen-presenting cells (APCs), such as dendritic cells, Langerhans cells, macrophages, B cells, and vascular endothelial cells. The T-cells are distinguished according to their T cell-receptor (TCR) and accessory molecules. The TCR is composed of an α and β chain or an γ and δ chain. Accessory molecules are the CD4 or the CD8 marker.

Antigen Presentation

Before further discussing the functions of the T cells, interest will be focused on the MHC and antigen presentation. MHC genes are organized in a gene complex of about 3.5 mb on chromosome six in man. Several classes of molecules are encoded in this gene complex, of which the MHC class I and class II molecules are central to antigen presentation. MHC class I molecules are formed by a variable polypeptide chain and a constant β -2 microglobulin. The MHC class II molecules represent heterodimers composed of variable α and β chains. Association of antigen with MHC molecules occurs inside the antigen-presenting cell and processing of foreign antigen to peptide fragments is an essential prerequisite for successful association and presentation. The complex of the MHC molecule and antigen peptide is transported to the cell surface and presented to T cells. MHC class I and II molecules can be subdivided into classical and nonclassical MHC molecules. Classical class I molecules are encoded in man by the HLA-A, -B, and -C

genes. These highly polymorphic molecules present processed peptides to CD8⁺ T cells. Nonclassical class I molecules are much less polymorphic and are encoded by HLA-E, -F, and -G. Their function in man is still ill-defined. In the mouse, the related Qa-1 and Qua-2 molecules present a restricted set of peptide antigens, for instance a fragment of lysteriolysin, to CD8⁺ T cells. Classical MHC class II molecules in man are encoded by HLA-DP, -DQ, and -DR. These molecules present processed peptides to CD4⁺ T cells. Nonclassical class II molecules, such as DMA and DMB, appear to support classical class II molecules in antigen presentation.

CD1 molecules form a non-MHC-encoded family of molecules involved in antigen presentation. As class I molecules, they are composed of a polymorphic α chain and β 2-microglobulin. So far, the isoforms CD1 a-e have been described in humans. Recently, it became apparent that CD1 molecules act as restriction elements in the presentation of several mycobacterial lipids, such as mycolic acid, and glycolipid antigens, such as lipoarabinomannan to T cells. Interestingly, CD1 molecules seem to present nonpeptide antigens not only to classical T cells but also to the recently described subsets of CD4⁺ NKT 1. 1⁺ and CD4–CD8– NK 1. 1⁺ T cells, that are also designated as natural killer T cells or NKT-cells. These NKT-cells, because of their capacity to produce interleukin four and other cytokines, can potentially influence the phenotype of the immune response to class II-restricted antigens. Their role in parasite infection, however, is still unclear.

Whether an antigen will be processed and presented with class I or class II MHC molecules appears to be determined by the route that the antigen takes to enter a cell. Exogenous antigen is produced outside of the host cell and enters the antigen-presenting cells, which degrade the exogenous protein within the phagosome into peptides of 12–15 amino acids length. The peptides are loaded into the cleft within the MHC class II molecules. The MHC class II peptides complex is then exported to the cell surface, where it is recognized by T-cells displaying CD4. CD4⁺ T cells recognize their antigen MHC class II restricted. Endogenous antigen is produced within the host cell itself. It is

either of host cell or of parasite origin. In the cytosol, proteasomes degrade endogenously synthesized proteins to peptides, which are then transported by particular transport-associated proteins, so-called TAPs to the endoplasmic reticulum. Here the peptides bind to MHC class I molecules. Thereafter the complex is exported to the cell surface. T cells displaying CD8 recognize the complex and are thereby stimulated. Therefore, they are said to be MHC class I restricted.

The great polymorphism of genes coding for MHC molecules allows man to bind and present a vast diversity of different peptides produced by the many parasite pathogens, to a large T cell repertoire, resulting in highly specific immune response.

T-Cell Mediated Responses

Next, the various T cells, to which antigen is presented will be discussed. In man, the T cell population in the periphery amounts to more than 10¹² cells, of which more than 90 % carry the α/β T-cell receptor (TCR) and less than 10 % the γ/δ receptor. The TCR associates with the variable region of the MHC-molecule which carries the antigenic peptide and the CD4 or CD8 molecules bind to the constant regions of the MHC molecules. Binding of the antigen/MHC-complex to the TCR results in the engagement of the CD3-complex, with subsequent signal transduction and T cell activation. This signal transduction is modulated by costimulatory effects induced by the accessory receptor/ligand pairs CD40/CD40 ligand or B7/CD28. CD40-mediated signals seem to affect primarily CD4⁺ T cells of the Th1 subtype, whereas the B7 costimulus trigger T cells of the Th2 subtype. The CD4⁺ T-cells according to their cytokine secretion pattern have been first subdivided by Tim Mossmann into the Th1 and Th2 family, Th1 cells producing IL-2 and IFN- γ , cytokines that serve as stimuli of T-cells or macrophages respectively, and Th2 cells producing IL-4, IL-5, and IL-10, that is T-cells that act as true helper cells for **B-cells**. The Th1 cells, via IFN- γ , seem to act as classical cells of delayed type of

hypersensitivity, i.e., of cell-mediated immunity for instance in the tuberculin reaction. Thus, they are of prime importance in the control of intracellular microorganisms such as toxoplasma, leishmania, mycobacteria, and others. By virtue of their IFN- γ production Th1 cells also downregulate Th2 cells. The Th2 cells, on the other hand represent the classical T helper cells, which are involved in the allergic reaction and in humoral immune responses. IL-4 is central to IgE production and IL-5 to IgA production and IL-10 downregulates Th1 cells. The subdivision of CD4⁺ T cells in Th1 and Th2 cells should however not be taken too strictly because during a developing immune response, T cells producing both Th1 and Th2 cytokines are found, and Th1 and Th2 cells might well coexist in the tissue.

Differentiation of Th0 cells into Th1 or Th2 is driven by cytokines produced by different cells of the immune system. IL-12 is the major player in the Th1 pathway and IL-4 driving the Th2 cells. Undoubtedly, the signals which in leishmaniasis are decisive for the initiation of a protective Th1 response versus a disease-promoting Th2 response, are by far not clear.

Besides CD4⁺ T cells, CD8⁺ cells are involved in immune reactions to most if not all intracellular parasites including plasmodia, toxoplasma, and leishmania. CD8⁺ cells function by their capacity to act as cytolytic killer cells as well as producers of cytokines such as IFN- γ , etc. CD8⁺ T cells lyse infected target cells by cell-to-cell contact subsequent to the recognition of the target peptide that is presented by class I molecules. Target cell lysis is mediated by two separate mechanisms. The first mechanism involves the secretion of perforins and granzymes by the killer cells, which both lead to osmotic lysis of the target cells. The second mechanism requires the cross-linking of the Fas-ligand and the cytolytic CD8⁺ cells with the Fas-antigen on the target cells with subsequent chromatin condensation, DNA fragmentation, and cell rupture. This mechanism induces ► [apoptosis](#), also known as programmed cell death, in the target cells. Cytolytic activity is most prominent in CD8⁺ T cells, however also some CD4⁺ T-cells have been shown to act as killer cells as in the case of ► [Toxoplasma gondii](#)-infected macrophages. CD8⁺ cells may act

in synergy with Th1 cells, when Th1 cells produce the cytokines IL-2 and IFN- γ and CD8⁺ cells contribute their cytolytic activity to the pathogen-eliminating process. Another type of T cells involved in the regulation of antiparasitic immunity are regulatory T cells (T_{reg}). Several types have been described based on their origin, generation, and mechanism of action, with two main subsets identified: “natural” Foxp3⁺CD4⁺CD25⁺ T_{reg}, which develop in the thymus and regulate self-reactive T cells in the periphery, and “inducible” T_{reg} (e.g., Tr1 or Th3 cells), which can develop in the periphery from conventional CD4⁺ T cells. Both types of T_{reg}, by virtue of their capacity to control the intensity of effector responses, have been shown to play a major role in the control of various parasitic infections.

Specific Aspects of Immune Responses to Helminths

Worms such as nippostrongylus, filaria, ► [ascaris](#), and schistosomes induce high levels of specific IgE antibodies and eosinophilia. This characteristic response pattern is caused by the particular ability of helminths to preferentially stimulate the Th2 subset of CD4⁺ cells, which secrete the cytokines IL-4 and IL-5, IL-4 involved in the production of IgE antibodies and IL-5 acting as growth factor for eosinophils. *In vitro* studies suggest that helminths opsonized with specific IgE antibodies are lysed by eosinophils that carry Fc receptors specific for IgE, the toxic product contained in the major basic protein of the eosinophils granules. This effector mechanism however does not relate to cell helminths infections as immunity to schistosoma induces Th1 cells and the production of IFN- γ , which results in activation of macrophages that directly delete the schistosome larvae by means of ► [nitric oxide](#) (NO).

Strategies of Evasion of Immune Mechanisms by Parasites

The capacity of parasites to survive and to persist in their hosts is a result of coevolutionary events

that enable the parasites to evade immune effector mechanisms. Most parasites have developed multiple ► [evasion](#) strategies to circumvent both innate and acquired defense mechanisms of the host, which will be discussed separately for each parasite.

Immunoassay

General Information

Immunological assays are available for measuring the humoral immune response after parasitic infections. For the detection and quantitation of

antibodies or antigens an immunoassay has to fulfill three basic requirements: highly specific, highly sensitive, and reproducible. The field of application and the quality of antigen/antibody available are the main variables which determine the choice for one specific assay. A test system may be adequate for population screening or for individual diagnosis. Ideally, it is a single definitive test which can equally detect antibodies in low-responders, in people with recently contracted infection or with high titers and clinical signs, and be suitable for a posttreatment follow-up.

The stability of the antigen-antibody complex (avidity) determines the success of all immunological assays.

IFA, EIA, WB

The indirect immunofluorescence (fluorescent antibody) assay (test) (IIFA, IFA, IIFAT, IFT) has long been the best choice in parasitology. By using cryosections from different developmental stages of helminths or free ► [protozoa](#) as antigens the test provides a satisfactory discrimination between specific and non-specific reactions. The differential binding of antibodies to different structures of the parasite or cell is used to distinguish between specific and nonspecific reactivity. Its disadvantage is subjective reading and labour intensiveness. Screening of a large population is practically impossible. The indirect haemagglutination test (IHAT, IHA) is applied for fast screening at low costs of several parasitic infections. A broad application of the indirect enzyme-linked immunosorbent (enzyme immunosorbent) assay (► [ELISA](#), EIA) has long been delayed by the use of nondefined, crude parasite extract antigens, resulting in a high degree of cross-reactivity. This disadvantage is now partly overcome by the availability of secretory/excretory (E/S) antigens, synthetic peptides and recombinant antigens. Still, the sensitivity and specificity of the ELISA vary considerably but it is an easy and fast alternative especially for population and herd screening and epidemiological studies. The western blot (WB, enzyme immunoblot, EIB), which provides a species or stage specific diagnosis is a

confirmation test and applied as the final diagnostic step when screening results are positive.

Other Test Systems

Today, only few laboratories still use immunodiffusion (ID), gel precipitation, complement fixation test (CFT), Sabin Feldman dye test (DT), counterimmunoelectrophoresis (CIE) or radioimmunoassay (RIA) in routine serodiagnosis. These test systems consume much antigen in comparison to the ELISAs, are less sensitive or use radio-labelled conjugates. Other test systems like card agglutination test (CATT), direct agglutination test (DAT), latex agglutination test (LA), carbon immunoassay (CIA), dot blot, and dip stick antigen assay were developed for a rapid, low cost screening under field conditions.

The rapidly increasing knowledge on immunology and molecular biology may result in a large scale production of characterized parasitic antigens applicable in different test systems. However, the suitability of each product for diagnostic purposes depends on the dynamics of the hosts immune response to that particular antigen.

Characteristics

IIFAT results depend not only on the kind of antigen used but also on its processing. Fixation is one of the most important steps (unfixed, formalin, acetone, methanol, heat, and others) to enhance or decrease the sensitivity or specificity of the test. The reading of the IIFAT requires a specific microscope. Reading of the slides by inexperienced staff may lead to different end-point titers due to subjective impressions. A new generation of IHATs using selected red blood cells of the 0 Rh- type for antigen cross-linking reduces the non-specific agglutination of erythrocytes and improves the specificity of this fast test system. ELISA is a suitable test system for the detection of both antigen and antibody. It is very sensitive and economic for testing a large number of serum samples within a relatively short time. The test principle allows many variations in the performance of the assay and the use of detection systems.

Direct and indirect, capture and dip stick and many other ELISA systems are described as efficient in different diagnostic fields. Reading of the test is normally by use of a photometer. In highly specific assays a discrimination between positive and negative results is also possible visually. Indirect ELISAs, which are predominately used in parasitology for antibody detection, measure antibody binding and not antibody levels and therefore provide only a limited quantitative information. The WB analysis demonstrates serum reaction patterns with antigen fractions of either a complex mixture or predefined extracts of parasites. It is used to demonstrate either an individual stage specific antibody response in follow-up studies or species specific reaction for the discrimination of infection with closely related parasites. The CATT is an easily and fast to perform low-cost system which uses the surface antigen of different *Trypanosoma*-species for antibody detection. It is applied as a screening tool for the (West) African ► [sleeping sickness](#) and animal trypanosomiasis caused by *T. brucei/congolense* and *T. evansi*.

Standardisation

Standardisation of immunological assays is a crucial problem in parasitology. The evaluation of the specificity, sensitivity, and negative/positive predictive value of an assay requires either a “gold standard” or a population based evaluation of numerous defined serum samples. Only the DT is an accepted “gold standard” for toxoplasmosis ► [serology](#). For other parasitic infections either parasite detection, disease, or some other immunological assay with proven diagnostic value are used as “gold standard.” Many home made or commercial test systems still work with undefined antigens. Also, reference sera are not available for all parasitic infections. Hopefully, standardization will improve with the availability of defined antigens.

Clinical Relevance

The clinical value of an immunoassay depends on its ability to allow the identification of an infected

individual on the results of single test. Ideally, the producer provides information on the positive and negative predictive value for his immunoassay. Due to a comparatively low demand for parasitological immunoassays in the low incidence “developed” countries test systems are often produced in parasitological laboratories. At present, only the serodiagnosis of toxoplasmosis is to a high degree commercialized and, in Germany, submitted to an official, external quality control. The choice of a suitable test system is therefore essential for a good diagnosis. For individual diagnosis a quantitative and specific measurement of the serum antibody concentration is required. The approximate antibody concentration is given either by end-point titers (IIFAT, IHAT), units, or absorbances (ELISA). The WB pattern can provide only semiquantitative, but highly specific results. In any case, an interlaboratory comparison of test results is only possible when identical assays are performed. The application of intra- and interassay quality controls by use of defined reference material is obligatory. For screening purposes a sensitive assay is preferred for primary diagnosis, followed by a more specific test for definitive diagnosis. Qualitative test results (positive/negative) will be sufficient for population screening or herd control. When interpreting test results it has to be considered that there is not only a population-based variability of the antibody responses to parasitic infections but also a great variability of the individual response depending on the parasite load and stage of infection. Finally, antibodies show variation among different techniques due to differences in multivalent binding.

The use of different test systems for seroepidemiological studies may result in different rates of seroprevalence achieved. These differences may reflect basic differences in the sensitivity or specificity between test systems. However, when direct parasite detection as “gold standard” for test evaluation is used, the resulting sensitivity depends not only on the experience of the investigator but also the frequency of sampling and the parasite load of the individuals tested. When disease is used as “gold standard” for test evaluation, a comparatively high seropositivity will result when the infective parasite exhibits a long ► [incubation period](#) and/or low ► [morbidity](#) rate. The clinical outcome

of parasitic infections depends also on the genetic predisposition of the infected individual. A positive test result in one immunoassay may therefore provide evidence for a yet unknown immunological recognition of the parasite, which is undetectable in other assays. Discrepant rates in the prevalence of *Toxocara canis*-antibodies in human serum were reported when either CIEP and IIFAT or E/S-ELISA was applied. The interpretation of unresolved positive values is carried out by considering the incubation period and possible pathological effect of each parasite.

Immunofluorescence Antibody Test (IFAT)

Diagnostic method.

Immunofluorescence Assay (IF)

Diagnostic method to detect parasitic cells.

Immunoglobins

Antibodies (IgA, IgE, IgM, IgG) that were produced by the B-lymphocyte system.

Immunomodulation by Parasitic Nematodes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Many parasitic nematodes are able to modulate host's immune reactions inducing the presence of an anti-inflammatory environment, which enables them to survive and to reproduce in immune-competent hosts. These immune-modulatory effects are due to the induction of regulatory

T-cells, of regulatory monocytes, and of macrophages and are accompanied by the stimulation of an increased production of reliable amounts of the anti-inflammatory cytokine-IL 10. Therefore such worms are considered as potential biologics for (future) treatment of inflammatory disorders in humans and animals. Actually patients, that suffer from autoimmune diseases (e.g., Morbus Crohn), showed a strong reduction of intestinal inflammation when ingesting larva-containing eggs of *Trichuris suis*. The larvae of this nematode hatch from the egg in human intestines, but do not reach fertility (adult stage).

Immunsorbent Agglutination Assay (ISAGA)

Diagnostic method.

Immunosuppression

Reduction of the activity of the immune system, e.g., due to HIV-infection, constant uptake of cortisone or co-infection with several parasites leads to the abnomal reproduction of some parasites.

5 years; thus, there are two factors, which can be obtained for each journal in a given scientific field (e.g., parasitology). Impact factors of course increase considerably, if in a given scientific field many journals are listed. Furthermore reviews are more often cited than original articles. This can be seen in the list of the top 20 journals (out of 35) in the field of Parasitology (obtained in 2013):

Top 20 journals in the category Parasitology (out of 35) are presented in Table 1.

Inappetence

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin, *in* = not, non; *appetencia* = wish.

This describes the symptom that some infected hosts feed less or even nothing (mostly during a weakness phase of the infected animal).

Incidence

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin, *incidere* = occurring.

This term describes the number of new infections, respectively, newly diseased hosts of parasites in a given period.

Incubation Period

Period up to the first appearance of clinical symptoms after an infection with ► [agents of disease](#). It is mostly not identical to ► [prepatency](#).

Incursive Zone

► [Geographic zones of occurrence of diseases](#): agents of disease are only found occasionally.

Indication

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

This Latin term describes the need of a special treatment after diagnosis of a disease (e.g., ► [malaria](#), ► [ascariasis](#), toxoplasmosis).

Indoor Feeding

Endophagy (e.g., mosquitoes, that take their blood meal inside of human dwellings).

Indoxacarb

Chemical Class

Carboxamide (oxadiazine carboxamide).

Mode of Action

Voltage-gated sodium channel modulator.

► [Ectoparasiticides: Blockers/Modulators of Voltage-Gated Sodium Channels.](#)

Inermicapsifer madagascariensis

Small only 5 cm long tapeworm of humans in East Africa, Asia, Cuba, and South America.

Inermicapsiferinae

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *inermis* = inner; *capsifera* = capsule.

Group of anoplocephalan cestodes. Some of them (e.g., *Inermicapsifer madagascariensis*) are parasites of rodents and humans. They are related to species of *Thysanotaenia* (e.g., *T. congolense*).

Infection

Moment of invasion/introduction/transmission of ► [agents of disease](#), which reproduce

inside the host. With respect to man there are main routes (e.g., eating plants infected with *Fasciola metacercariae* or pig meat with ► [cysticercus](#) of ► [Taenia solium](#) or uncommon, but also highly effective ones (e.g., eating infected raw liver in the case of *Fasciola* or imported sweet potatoes covered with eggs of *Taenia solium*, as was shown in a Jewish population).

Infection Dosis

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

It is widely accepted that the entomological inoculation rate (= EIR) is significantly correlated with the introduction of a patent infection with *Plasmodium falciparum* and other parasitic species. However, the question arose: how many sporozoites are needed to establish a patent infection? With respect to *P. vivax* in humans, it was published that as few as 10 sporozoites can be sufficient to establish a patent infection, while volunteer infections with *P. falciparum* showed that bites of five mosquitoes bearing more than 10 sporozoites are required to lead to a successful infection. These findings would indicate that in the case of *P. falciparum*, a higher rate of EIR is needed to spread malaria in a given region. In other coccidian parasites (► [Eimeria](#), [Toxoplasma](#), ► [Sarcocystis](#), ► [Isospora](#), *Cryptosporidium*, etc.), it is widely unknown how many oocysts are needed to establish a patent infection.

Name

Latin, *inficere* = infect.

- **Alimentary infections:**
Parasites are inside food.
- **Autoinfections:**
Repeated self-infection with parasites of the same host.
- **Endogenous infections:**
Parasites wander from one organ to another inside the same host.
- **Exogenous infections:**
Parasites enter from outside the body.
- **Inapparent infections:**
Parasites do not induce clearly remarkable symptoms.
- **Horizontal infections:**
Transmission of parasites between hosts of the same generation/group.
- **Iatrogenic infections:**
In this case the medical doctor or veterinarian transports a parasite from one group of patients to another.
- **Inoculative infections:**
Agents are transmitted by bites of vectors.
- **Connatal infections:**
Infections during birth.
- **Contaminative infections:**
Infections due to infectious stages, e.g., in feces, blood, etc.
- **Latent infection:**
Infections with no detectable symptoms (e.g., due to lack of methods).
- **Neonatal infections:**
Infections of newborn animals or humans.
- **Peroral infections:**
Infections by oral uptake.

- **Percutaneous infections:**
Infections by penetration of the skin.
- **Perinatal infections:**
Infections in the periods before and after birth.
- **Phageous infections:**
Hosts ingest occasionally infected vectors.
- **Prenatal infections:**
Infections of the fetus inside the placenta.
- **Primary infections:**
First infection.
- **Reinfections:**
Repeated infections.
- **Recidive infections:**
Infections, which show again symptoms of disease when hosts suffer from phases of immunosuppression.
- **Secondary infections:**
Infections of a host which has already another infection.
- **Superinfections:**
Repeated infections with the same parasite from another host.
- **Transmammal infections:**
Infections of babies due to drinking of mother's milk.
- **Vertical infections:**
Infections are transmitted from one host generation to the next one.

Infectious Larvae of Nematodes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In ► [nematodes](#) the larva 3 acts as an infectious stage. In general these stages are ingested with food, while being attached at plants. These stages are mostly surrounded by a sheath (Fig. 1). However, the larvae 3 of ► [Strongyloides](#) are not sheathed when entering their hosts.

Inhibitory-Neurotransmission-Affecting Drugs, Fig. 2 Model of the action of piperazine on the GABAergic neurotransmission

Molecular Interactions

Piperazine (Fig. 1) induces a reversible paralysis of *Ascaris suum* *in vitro* by exerting hyperpolarizing effects, thus acting as a selective GABA agonist (Fig. 2). The average duration of piperazine-induced channel openings is 14 ms, and is thus shorter than the GABA-produced openings with 32 ms. Piperazine is about 100 times less potent than GABA in *A. suum*. The difference in potency correlates with the need for higher piperazine concentrations to achieve a similar opening rate to GABA. The *Ascaris* GABA receptor is pharmacologically distinguished from the vertebrate GABA_A

receptors. The action becomes potentiated by the presence of a high pCO₂ probably by interaction of CO₂ with the heterocyclic ring of piperazine which partially substitutes for the carboxylgroup of GABA.

Macrocyclic Lactones

Important Compounds

Ivermectin, Abamectin, Doramectin, Eprinomectin, Latidectin, Milbemycin oxime, Moxidectin, Selamectin.

Synonyms

Ivermectin: Baymec, Ivomec, Ivomec-Premix Ivomec-S, Cardomec, Equell, Eqvalan, Furexel, Heartguard 30, Heartgard Chewable, Mectizan, Oramec, Rotectin, Strongid, Zymectrin; in: Ivomec-P, Heartgard Plus.

Abamectin: Avomec, Duotin, Enzec; in: Equimax.

Doramectin: Dectomax.

Eprinomectin: Eprinex.

Latidectin: Lifenal

Milbemycin oxime: Interceptor, Interceptor Flavor Tabs; in: Sentinel.

Moxidectin: Cydectin, Equest, Pro Heart, Quest.

Selamectin: Revolution, Stronghold.

Clinical Relevance

The group of these macrocyclic lactones is subdivided into two groups, the **avermectins** and **milbemycins**. To the avermectin anthelmintics belong avermectin (explored 1975), ivermectin (marketed 1980), abamectin (1980), doramectin (1993), eprinomectin (1996), selamectin (1999) and latidectin (2005). To the milbemycin anthelmintics belong milbemycin (explored 1973), milbemycin oxime and moxidectin (1993). Avermectin is produced by *Streptomyces avermitilis*, an actinomycete strain. Avermectin was isolated in 1975 and its antiparasitic activity discovered in mice infected with *Nematospiroides dubius*. The components avermectin B_{1a} and B_{1b} exert the highest anthelmintic activities. The chemical reduction leads to dihydro-derivatives with low toxicity. The mixture of 80 % dihydro avermectin B_{1a} and 20 % B_{1b} is named **ivermectin**.

Macrocyclic lactones are applied as broad-spectrum anthelmintics and ectoparasiticides in dogs, horses, cattle, sheep, pigs (Tables 1 and 2, ► [Microtubule-Function-Affecting Drugs](#), Table 1, 2). Ivermectin is the drug of choice against ► *Strongyloides stercoralis* infections in immunosuppressed patients. In addition, this drug is used for ► [heartworm prophylaxis](#), in human onchocerciasis it is the drug of choice and it is of growing importance in ► [lymphatic filariasis](#) (e.g., ► *Wuchereria bancrofti* infections) as single

drug or in combination with DEC or albendazole (Table 1). It has microfilaricidal effects and leads to a suppression of embryogenesis in human onchocerciasis. It was introduced to Onchocerciasis Control Program of WHO in 1987 as Mectizan. In addition, ivermectin has some activity against male ► *Onchocerca volvulus* in man as well as against microfilariae of *W. bancrofti*, ► *Loa loa*. Ivermectin activity can be observed against *Litomosoides carinii* microfilariae in the circulating blood but not against microfilariae in the pleural cavity. Ivermectin has some *in vitro* activity against filarial parasites, e.g., ► *Onchocerca* spp. There is generally a great discrepancy between the good *in vivo* efficacy and the minor *in vitro* effects. In general, treatment with ivermectin is not accompanied by severe side effects.

Molecular Interactions

Macrocyclic lactones act at the junction of ventral cord interneurons and motoneurons resulting in the immobilization of nematodes and at the neuromuscular junction of arthropods causing paralysis. Macrocyclic lactones are taken up by many gastrointestinal and filarial nematodes via the cuticula and presumably with equal importance by oral ingestion (► [Acetylcholine-Neurotransmission-Affecting Drugs](#), Fig. 3), while in blood-sucking parasites (► *Haemonchus contortus*, arthropod ectoparasites) the oral absorption is by far more important. This view is supported by the observation that macrocyclic lactones exert greater activities against sucking ► [lice](#) (*Haematopinus eurysternus*, *Linognathus vituli*) than biting lice (*Damalina bovis*). They also have high efficacy against ► [mites](#) (*Sarcoptes scabiei* var *bovis*), which are known to be blood consumers.

The mode of action of avermectins and milbemycins relies on the opening of the chloride ion channels in the neuronal membranes of nematodes and the muscle membranes of arthropods (Fig. 3). Thereby, cells become hyperpolarized and can no longer respond to incoming stimuli. All the physiological effects of avermectins and milbemycins can be reversed by picrotoxin, a

Inhibitory-Neurotransmission-Affecting Drugs, Fig. 3 Model of the drugs affecting neuromuscular transmission by inhibitory neurotransmitters in protostomes

specific blocker of the chloride ion channels. There is an ivermectin-induced increase of chloride permeability of nerve and muscles membranes of invertebrates observable. The structure and regulation of chloride ion channels of nematodes on the molecular level is unclear at present and also the identity of the target ion channel is

controversial. Results from experiments with crayfish and *Ascaris suum* reveal that there is an interaction with receptors at chloride channels. The action is obviously not mediated by GABA-gated chloride channels. Expression experiments with *Xenopus* oocytes lead to a proposed action of avermectins on a glutamate-gated chloride

channel (GluCl). Genes encoding ivermectin-sensitive glutamate-gated chloride channel subunits could be isolated from ► *Caenorhabditis elegans*. Moreover, the avermectin-binding site could be purified from *C. elegans*. A 1.8–2.0 kbp mRNA of *C. elegans* encoding a chloride channel with sensitivity to both ivermectin and glutamate could be identified. The channel is presumably a pentamer similar to the nicotinic receptor and is selectively permeable for anions (chloride). The pentamer consists presumably of GluCl- α subunits with a glutamate-binding site and a GluCl- β subunit which contains the ivermectin-binding site. Molecularbiological experiments reveal that the GluCl- β subunit of the glutamate-gated channel is expressed in the pharyngeal muscle of *C. elegans*. There are considerable identities of α - and β -subunits of the glutamate-gated ion channels with the α - and β -subunits of mammalian GABA and glycine receptors.

According to a hypothesis the pharyngeal pumping of nematodes is inhibited by ivermectin. In the pharyngeal muscle of *A. suum* a potentiation of the action of glutamate on glutamate receptors that gate chloride channels by ivermectin analogues could be observed. The hyperpolarization of the nerve and muscle membranes leads to a flaccid paralysis of the parasites. The CNS side effects of ivermectin are explained by the strong action on the receptors in rat brain through potentiation of GABA- and benzodiazepine-binding to open the channel. Nevertheless the relatively safe use of avermectins is due to the inability to cross the blood-brain barriers into the CNS in mammals with the exception of Collies. Moreover, the selectivity of macrocyclic lactones is due to different neurotransmitter functioning of glutamate in invertebrates (protostomes) where it acts as an inhibitory neurotransmitter in contrast to vertebrates where glutamate acts as an excitatory neurotransmitter.

Macrocyclic lactones like milbemycin oxime have only slight inhibitory and stimulatory concentration-dependent effects on the motility of filariae such as ► *Dirofilaria immitis*. It is assumed that definite host factors are required, which are independent of a specific immune status

of the host. In ► *Acanthocheilonema viteae* an ivermectin-mediated cell adherence to the living microfilariae is observable and also cellular cytotoxicity by complement activation via the alternate pathway and/or antibodies. *L. carinii* microfilariae are killed without direct contact between cells and larvae. Here a very short-living mediator, which can be inhibited by the arginin-analogs such as N^G-monomethyl-L-arginine and L-canavanine, seems to be involved in the drug's action. Leucocytes are also required for the *in vitro* efficacy of ivermectin against microfilariae of *Dirofilaria immitis*. The immobilization of the larvae is necessary for cell adherence or cellular toxicity similar to ivermectin-induced paralysis of *Acanthocheilonema suum*. In addition, the paralysis of microfilariae of *O. volvulus* presumably facilitates the phagocytic cell-trapping. The effects of ivermectin on adult worms are not fully understood to date. Electron microscopic studies on *Acanthocheilonema viteae* reveal a vacuolization and an increased electron density in all organs beginning 8 days after treatment. In *L. carinii* a degeneration of intrauterine stages and an extreme folding of the uterine wall can be observed accompanied by a generally increased electron density.

Resistance

Resistance against macrocyclic lactones is probably inherited by a single dominant allele in *Haemonchus contortus*. The mechanism of ivermectin resistance on the molecular level is still unknown. Membranes of ivermectin-resistant and -susceptible larvae of *H. contortus* contain similar numbers of ivermectin-binding sites with the same affinity characteristics. It could recently be shown that ivermectin resistance may be caused by an altered P-glycoprotein homolog in *H. contortus*. Thereby the expression of P-glycoprotein mRNA is higher in the ivermectin-resistant *H. contortus* strain than in the susceptible strain. This multidrug-resistance mechanism can be reversed by verapamil and there is an increased efficacy of ivermectin and moxidectin against moxidectin-resistant *Haemonchus* in jirds (*Meriones unguiculatus*) in the presence of verapamil. The disruption of the *mdr1a* gene, which encodes P-glycoprotein in

mice, results in hypersensitivity against ivermectin. In another report an involvement of P-glycoprotein in ivermectin resistance in *H. contortus* was excluded. Now there exists a *Caenorhabditis elegans* mutant with a high level of ivermectin resistance, which can serve as a tool for further investigations of alterations in the glutamate/ivermectin chloride channel receptor and mechanism of ivermectin resistance in future.

Cyclic Octadepsipeptides

PF1022A

Synonyms.

Clinical Relevance

This compound has potent antinematodal properties against ► *Toxocara canis*, *T. cati*, and ► **hookworms** in dogs and cats and *Trichuris vulpis* in dogs. In addition, it has high efficacies against gastrointestinal ► **nematodes** in horses, sheep, chicken, and rodents.

Molecular Interactions

PF1022A is a 24-membered cyclic depsipeptide isolated from *Mycelia sterilia*, a fungus which belongs to the ► **microflora** of the plant *Camellia japonica*. Recently the chemical synthesis of PF1022A and also the radiolabelled compound have been reported. The anthelmintic action on the molecular level remains obscure to date. It appears that it exerts its activity by interfering with the neuromuscular transmission of nematodes. At low concentrations, the motility of ► *Angiostrongylus cantonensis* is depressed, and picrotoxin, bicucullin, and Ca^{++} can antagonize the action. Thus, the action is explained by an antagonism of acetylcholine receptors and/or gabaergic mechanisms. It could also be shown that PF1022A has a high affinity binding to the GABA_A receptor in *Ascaris suum*.

Recent experiments show that PF1022A and emodepside bind to a latrophilin-like receptor in the parasitic nematode *Haemonchus contortus* and the free-living nematode *Caenorhabditis elegans*.

Emodepside

Synonyms

PF1022–221, Bay 44–4400, emodepside as part of the anthelmintic combination emodepside/praziquantel in Profender Spot-On® for cats.

Clinical Relevance

Anthelmintic research of the class of cyclic octadepsipeptides to which emodepside belongs started at the beginning of the 1990s. PF1022A, the starting material of emodepside, is a natural secondary metabolite of the fungus *Mycelia sterilia*, which belongs to the microflora of the leaves of *Camellia japonica*. PF1022A consists of four N-methyl-L-leucins, two D-lactic acids and two D-phenyllactic acids. These molecules build up a cyclic octadepsipeptide with an alternating L-D-L configuration. Emodepside is a semisynthetic derivative of PF1022A, which contains a morpholine attached in para-position at each of both D-phenyllactic acids.

Emodepside is effective against a wide variety of nematodes in cats, dogs, sheep, cattle, horse, poultry, mice, and rats. In cats after spot-on application of the all de-wormer Profender®, emodepside is highly efficacious against *Toxocara cati* and *Ancylostoma caninum* (► **Microtubule-Function-Affecting Drugs**, Table 2). In addition to its effects against gastrointestinal nematodes emodepside shows activities against lungworms in cattle, different larval stages of filariae in rodent models, and *Trichinella spiralis* larvae in mice.

Molecular Interactions

Emodepside binds to a presynaptic latrophilin-like receptor in the parasitic nematodes *Haemonchus contortus*, *Ostertagia ostertagi*, *Cooperia oncophora*, *Ancylostoma caninum*, and the free-living nematode *Caenorhabditis elegans*. Binding of drug to the latrophilin-like receptor is followed by the activation of a presynaptic signal transduction cascade (Fig. 4). The activation of $\text{Gq}\alpha$ protein and phospholipase- $\text{C}\beta$ leads to mobilization of diacylglycerol (DAG). DAG then activates UNC-13 and synaptobrevin, two proteins which play an important role in

**Inhibitory-
Neurotransmission-
Affecting Drugs,**

Fig. 4 Proposed mechanism of action following activation of a presynaptic latrophilin receptor by emodepside. *PLC* Phospholipase, *PIP2* phosphatidylinositol-4,5-bisphosphate, *DAG* diacylglycerol

presynaptic vesicle functioning. This finally leads to the release of a currently unidentified neurotransmitter. The transmitter (or modulator) exerts its effects at the postsynaptic membrane and induces a flaccid paralysis of the pharynx and the somatic musculature in nematodes.

Insect Growth Regulator

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Product/compound that acts by interfering with the development of eggs or other stages of potential ectoparasites or pests.

Innate Immunity

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the first line, nonspecific defense of a host against an invaded pathogen based on the recognition of conserved pathogen motifs during its evolution (phylogeny).

Insect Hormones: Used by Parasites to Steer Their Hosts

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Primary hormones of insects are so-called juvenile hormones which are secreted by the corpora allata to maintain a larval stage, and ecdysone, which is excreted by the prothoracic glands or ring glands in ► [Diptera](#) and initiates moulting after its conversion to 20-hydroxyecdysone. Since many parasite insects – especially several [Diptera](#) and

Inoculation

From Latin: *oculus* = eye. Experimental infection of a host.

Hymenoptera – live in their host's hemolymph filling the body cavity, they exploit these hormones to their advantage. However, they are also able to excrete own hormones and in addition various other substances which steer the host's development and behavior to their own support.

Classification

Class of ► [Arthropoda](#).

General Information

The Insecta are the largest group of animals with respect to the number of species (~773,000) and to individuals. The classification is based on the original occurrence (► [Pterygota](#)) or absence (► [Apterygota](#)) of wings. The further developed subclass Pterygota includes all important parasitic species; some of them, however, have apparently lost their primary wings during adaptation to parasitism (e.g., ► [fleas](#)). Insects may act as ectoparasites when sucking blood on the surface of their hosts (e.g., ► [mosquitoes](#)), or may even become endoparasites when entering the skin, and the intestinal and/or respiratory tracts in a variety of hosts (e.g., flies leading to myiasis; ► [Dermatobia hominis](#)). In addition to this method of parasitism the insects may be directly or indirectly involved

in the life cycles of a large number of parasites. These insects are encountered:

- as true intermediate or final hosts of important parasites of humans and animals (e.g., Protozoans, ► [Platyhelminthes](#), ► [Nematodes](#))
- as true vectors of pathogens (including an inner production phase) such as bacteriae, rickettsiae, and viruses (e.g., fleas, body ► [lice](#))
- as mechanical vectors of some parasites (transporting parasitic stages via mouthparts) (e.g., *Entamoeba*-, *Giardia* cysts)

The body organization of parasitic insects is very often closely adapted for its peculiar way of life and the special needs of feeding. However, the following basic features are commonly recognized:

- The body shows a clear segmentation into the head (caput), breast (thorax), and trunk (abdomen), each part consisting of several specific segments (visible from outside or not).
- The chitinous exoskeleton is regularly molted during growth (Fig. 1).
- The caput, the segments of which form a strong capsule, is endowed with a pair of dorsal, segmented antennae (Fig. 2) and 3 pairs of ventral mouthparts (mandibles, maxillae 1 and 2), the latter being strongly adapted for their special way of feeding. In general, eyes are compound and located close to the basis of the antennae; the eyes are mostly composed of numerous single ommatidia, in rare cases (e.g., fleas) only one or a few ommatidia are present.
- The thorax always consists of 3 segments (pro-, meso- and metathorax), which each bear ventrally a pair of legs (e.g., the name hexapoda means six feet). These legs are segmented and composed of 5 distinct parts (coxa, trochanter, femur, tibia, and tarsus); the tarsus comprises several single segments and is equipped with species-specific holdfast systems, claws, etc.
- The meso- and/or metathorax may form typical membranous wings (formed by the ► [integument](#)) which are moved by strong inner (mostly indirect) muscular systems. Wings, however, are reduced secondarily in some groups (e.g., fleas, bedbugs, lice).

Insects, Fig. 1 Diagrammatic representation of the reproductive system of a male dog flea (► *Ctenocephalides canis*) (AH accessory glands, DE ductus ejaculatorius, HO ► testis, NH “epidydimis” (vas efferens), PE penis)

- The abdominal segments form no ventral extremities except for some specific copulatory appendages. Inside the abdomen important systems of the insects are found (gonads, heart, excretory system, Malpighian tubules, etc.).
- Respiration of insects proceeds using a large, widely branched tracheal system reaching up to the surface of single cells.
- The inner side of the gut of many species is lined by a single or several chitinous ► **peritrophic membranes** (Fig. 3), which are a considerable obstacle for some parasites on their way to the intestinal wall and to the body cavity.
- In general, the fertilized eggs of insects show a total, superficial cleavage, which in the Pterygota is followed by 2 different types of larval development. Hemimetabolic development proceeds as constant ► **metamorphosis** via molting larvae (also named nymphs), which resemble the final adult stage and become sexually mature after the last molt. Holometabolic development is characterized by an additional ► **pupa**, which gives rise by molt to the sexually mature adult (► **Imago**). The pupa may be completely inactive (e.g., fleas, flies) or may be motile (as in ► **mosquitoes**), but never feeds.

System

Considering exclusively the parasitic groups, the following summarized classification is in general accepted:

- Class: Insecta
- Subclass: Apterygota (wingless forms)
- Subclass: Pterygota (primarily with wings which may become reduced in some groups)
- Order: ▶ **Phthiraptera** (animal lice)
 - Suborder: ▶ **Anoplura** (bloodsucking lice)
 - Suborder: ▶ **Mallophaga** (chewing lice)
- Order: ▶ **Rhynchota** (▶ **Hemiptera**, ▶ **Bugs**)
 - Family: ▶ **Reduviidae** (predacious bugs)
 - Family: ▶ **Cimicidae** (bedbugs)
- Order: ▶ **Diptera** (forewings fully developed, hindwings as halteres)

- Suborder: Nematocera
 - Family: ▶ **Phlebotomidae** (▶ **Sand Flies**)
 - Family: ▶ **Culicidae** (▶ **Mosquitoes**)
 - Family: ▶ **Ceratopogonidae** (▶ **Midges**)
 - Family: ▶ **Simuliidae** (▶ **Blackflies**)
- Suborder: Brachycera
 - Family: Tabanidae (horseflies, deerflies, clegs)
- Suborder: Cyclorrhapha
 - Family: ▶ **Muscidae** (houseflies, stable flies)
 - Family: Calliphoridae (bluebottles, blowflies)
 - Family: Sarcophagidae (meat flies)
 - Family: ▶ **Glossinidae** (tsetse flies)
 - Family: Oestridae (nostril flies)
 - Family: Gasterophilidae (stomach botflies)
 - Family: Hypodermatidae (warble flies)
 - Family: ▶ **Hippoboscidae** (keds, louse flies)
- Order: ▶ **Siphonaptera** (▶ **Aphaniptera**, ▶ **Fleas**)

Reproduction

Most parasitic insects are ▶ **oviparous**. In some genera (e.g., ▶ **Oestrus**, ▶ **Sarcophaga**) eggs are retained until larvae are ready for hatching (▶ **Ovoviviparous**). A few species (e.g., some ▶ **Musca** spp., ▶ **Glossina** spp.) are ▶ **larviparous**, laying more or less highly developed larval ▶ **instars**. Even ▶ **pupiparity** can be found (e.g., *Melophagus ovinus*) when immobile, fully developed larval instars pupate during deposition. The ontogeny of parasitic insects occurs either as ▶ **hemimetabolous development** or ▶ **holometabolous development**.

Reproductive Organs

Insects are typically ▶ **dioecious**, this being regulated by different sex chromosomes. ▶ **Sexual dimorphism** becomes evident with the development of the abdominal copulatory appendages.

Insects, Fig. 4 Diagrammatic representation of a typical insect cuticle (BL basal lamina, CE cement layer, EC epicuticle, EN endocuticle, EP epidermis, EX exocuticle, GC gland cell, GD, gland ductus, HM hemocyte, OE oenocyte, P pore channel, PO polyphenol layer, W wax layer)

In general the female genital pore is situated ventrally at the posterior margin of the 8th segment (sternite), whereas the male pore is situated along the ventral midline of the 9th, which also forms the copulatory appendages.

The **male** system (e.g., fleas; Fig. 4) is situated dorsal to the intestine. It consists of 2 testes, each with 1 to several sperm-producing follicles, 2 vasa deferentia (each with an enlargement, the seminal vesicle), 2 accessory glands which join the vasa deferentia, a single ejaculatory duct formed by fusion of the vasa deferentia, a penis which communicates with the exterior via the genital pore, and several species-specific external copulatory appendages.

The **female** system (Figs. 5 and 6) has 2 ovaries. These are composed of a species-specific number of tube-like ovarioles, which differ with respect to the location of the vitelline cells, but which all include a string of ► **oocytes**, of which the one nearest the oviduct is the first to mature. In the posterior part the ovarioles unite to form the calyx, which opens into the lateral oviduct. The female system also has 2 lateral oviducts, a common central oviduct, a common vagina often leading into an exterior ovipositor, a single

spermatheca (seminal receptacle, which opens into the vagina as does a spermathecal gland) and paired accessory glands that empty into the vagina.

Gametogenesis and Fertilization

The testes of insects produce, via a meiosis, numerous filariform haploid ► **spermatozoa**, which are finally endowed with a head containing the nucleus and a midregion including the masses of ► **mitochondria**, and which end in a long motile flagellum extending from the base of the nucleus. During copulation these spermatozoa are transferred directly or via a ► **spermatophore** into the female system. The ovary (► **Germarium**) of the latter produces mature eggs which in Pterygota contain centrally located ► **yolk** masses (i.e., centrolecithal eggs) and which are surrounded by an eggshell provided with a thin place for fertilization (► **Micropyle**).

Single mating is the rule in insects, and it involves internal insemination and filling of the ► **spermatheca**. When the mature ovum is shed, the empty ovarian sac contracts, but often remains as a remnant body, thus indicating the individual

Insects,

physiological age (this is helpful, e.g., in populations of *Glossina* spp., ► *Simulium* spp., and ► *Anopheles* spp.). When the ova pass the openings of the ► *spermatheca*, fertilization occurs and the final egg shape is regulated by the excretions of the accessory glands. Several spermatozoa enter totally via the ► *micropyle*. During the time needed by the spermatozoa to pass through the yolk, the female nucleus divides meiotically into 4 haploid nuclei. Of these 3 nuclei degenerate, whereas the fourth fuses with the nucleus of the spermatozoon that arrives first. This leads to the diploid set of ► *chromosomes*, the number of which varies among species and even races, e.g., *Culex pipiens* has 6 chromosomes ($= 2n$). This egg starts the embryonation, which in parasitic insects occurs superficially since the cells initially divide as a surface layer on the centrally situated yolk.

Integument

The ► *cuticle* covers the whole body of insects and the anterior and posterior parts of their intestine (Fig. 3). The nonliving cuticular masses are excreted by an epidermis (Hypodermis), which consists of a single layer of cells resting on a basal lamina (basement membrane; Fig. 1). This hypodermis includes a variety of different cells such as the typical epidermal cells, hair-forming cells (tomogen and trichogen cells), oenocytes, sensory cells, and various dermal gland cell types; the latter may form long tubular cytoplasmatic protrusions, which extend close to the surface, thus giving rise to the “cuticular pores” seen in sections (Fig. 1). The “normal” hypodermal cells produce the nonliving cuticle, which is composed of 3 distinct layers, epi-, exo- and endocuticle. The innermost layer is the thick endocuticle which includes ► *chitin* filaments and nontanned protein and thus remains flexible. The exocuticle is also relatively thick and represents the main component of the exoskeleton, since it is built up of chitin and tanned protein (sclerotin). On its outside the exocuticle is covered by the epicuticle, which in general is only 1–3 µm thick; the epicuticle is composed of an inner

layer of lipoprotein (► *Cuticulin*), a polyphenol layer, a wax layer, and finally is covered by a cement layer, thus providing waterproofing and survival in atmospheres that are not water-saturated.

This typical construction of the cuticle, which is regularly molted (► *Diptera*, Fig. 1), is altered at places where flexibility is needed. Thus, the membranes between sclerites (segments) lack the rigid exocuticle, and the endo- and epicuticle remain smooth to allow body flexion. Molt (► *Ecdysis*) occurs due to activity of hormones such as ecdyson, neotenin, etc. (► *Hormones*).

Musculature

The quickly acting muscles of insects as well as arthropods are always of the cross-striated type (Fig. 7a), showing the characteristic arrangement. They are no longer parts of the ► *body cover*, but are segmentally arranged and insert at intersegmental ► *tendons*. The muscular bundles may run in all directions, but in many cases have antagonistic counterparts. Extremities such as the mouthparts, legs, and wings (if present at all) possess muscles that are independent of those of the body, thus allowing countermovements. In addition to these quickly acting striated muscles, the intestine, some other internal organs and external appendages are lined by muscles of the smooth type containing relatively few filaments.

Intestine and Food Uptake

The asymmetrical tube-like gut of adult insects is oriented through the midregion of the body and consists of 3 main portions (Figs. 3 and 8): (1) stomodeum (foregut), (2) ► *ventriculus* (midgut), and (3) proctodeum (hindgut).

The stomodeum opens anteriorly through the mouth, which is located in the preoral cavity and connected with the excretory ducts of the paired salivary glands. The mouth is armed by (originally) 3 pairs of ventral appendages of the head (caput) modified as mouthparts which are species-specific and adapted to the particular

Insects,

Fig. 7 Diagrammatic representation of the transmission of ► **plague** bacteria during blood meals of a flea (e.g., ► *Xenopsylla cheopis*). (a) The flea sucks bacteria (b) among red blood cells at an infected host. (b) Between 2 blood meals the bacteria reproduce inside the flea and block the opening of its stomach. (c) During the next blood meal the flea regurgitates intestinal contents (with bacteria) into the other host (according to Geigy)

feeding habits. In parasitic insects the following types of mouthparts can be found:

- The chewing type (e.g., Mallophaga, biting lice) is considered the most basic one, since it is common in many free-living species (beetles, ants, etc.) and consists of large mandibles (to masticate the food), and a pair of separate maxillae I and of fused maxillae II (i.e., labium). Both types of maxillae serve to push the minced food particles into the mouth.
- The sponging or lapping type is found in most nonbiting dipterans (e.g., *Musca*, *Calliphora*; Fig. 2). The mandibles and maxillae are nonfunctional, whereas the remaining parts form a ► **proboscis** with a superficially enlarged tip, the surface of which consists of halfmoon-shaped plates (labella) surrounding the mouth. Foods dissolved by excretion of saliva are ingested in liquid form via the superficial capillary channels, which lead to the mouth.

Insects, Fig. 8 SEM-micrographs of the mouthparts of dipteran bloodsuckers. Both hide their stylet-like injectors in a protrudible sheath. (a) The tsetse fly ► *Glossina*

morsitans. ×50. (b) The ► Yellow fever transmitting mosquito *Aedes aegypti*. The antenna of the females (like in the present picture) possess only a few lateral hairs (×30)

- The cutting-sponging (lapping) type is characteristic of tabanids (Fig. 2). Their mandibles are modified as sharp blades and the maxillae appear as long stylets; both may cut the host's skin. Bloodsucking (lapping) occurs via a sponge-like labium together with the hypo- and epipharynx (i.e., protrusions of the body wall).
- Piercing-sucking types are present in many bloodsucking ectoparasites such as mosquitoes (Fig. 9), tsetse flies, other flies (Fig. 2), lice (► *Lice*, Figs. 1, 3), bedbugs (► *Bugs*, Fig. 2), or fleas (Fig. 3, ► *Fleas*, Fig. 3). Modifications found in the different groups are so great that the homologies between mouthparts can only barely be recognized. In any case, however, 2 different channels are formed by the mouthparts, the larger one is used as a food canal, while the other conveys saliva containing an anticoagulant and several other substances.

The size and shape of the skin-piercing mouthparts are related to the 2 different methods of blood feeding. The mouthparts of vessel or capillary feeders such as some ► *bugs* (*Cimex* spp., *Rhodnius* spp.), fleas, and some mosquitoes (e.g., *Anopheles* spp.) are injected into the lumen of capillaries of suitable caliber, whereas ► *pool feeders* such as most nematocerans (e.g., Simuliidae), some flies (e.g., ► *Stomoxys* spp., Glossinidae), and tabanids destroy peripheral

blood vessels with their armed mouthparts, wait until sufficient blood has collected inside the wound, and then ingest it rapidly, thus visibly distending their stomach.

In parasitic bugs, fleas, lice, tabanids, and some flies (e.g., muscids, tsetse flies), both sexes are hematophagous, whereas in nematocerans such as culicids, simuliids, phlebotomids, and ceratopogonids only the females possess piercing-sucking mouthparts and the males feed exclusively on moisture, etc. or even do not feed.

The mouth opens into the buccal cavity and leads to the pharynx, which eventually acts as a muscular pump and conveys the food down the narrow esophagus to a crop which acts as a storage system. The crop, which in dipterans is a blind-ending diverticulum from the esophagus, in general opens into the narrower valve-like proventriculus, which prevents regurgitation of food from the midgut (cf. Figs. 5 and 8).

- The ventriculus (midgut, stomach in part) is the main digestive organ and in several parasitic insects is lined with an inner nonadherent tube of chitinous components (peritrophic membrane), which is of great importance in the transmission of pathogens (cf. Fig. 3, ► *Lice*, Fig. 3). The midgut may be divided into different regions with concentrative, digestive, and absorptive functions. In nematocerous larvae and some other insect groups additional gastric

Insects, Fig. 9 SEM micrographs of heads of dipteran bloodsuckers. (a, b) ► *Tabanus* sp.; lateral aspect and magnification of the cutting mouth parts (b) (a $\times 40$, b $\times 60$). ceca may increase the surface area for absorption.

The proctodeum (hindgut) extends posteriorly from the midgut, from which it is separated by a pyloric sphincter. The main function of the hindgut is the resorption of water from the feces and the urine. The components of the latter come from the Malpighian tubules, which open at the border between the mid- and hindgut. The hindgut usually has an intestinal part, followed by the colon

and rectum, and finally opens into the ventrally located anus (Fig. 8).

Excretory System

In insects the Malpighian tubules are of ectodermal origin and function as the main excretory system; they are blind-ending, tube-like appendages of the intestine and open at the border between the mid- and hindgut (Fig. 8). Apparently

the waste-containing hemolymph circulates in the hemocoel near these structures, the number of which is species-specific. The main function is the absorption of uric acid (as sodium and potassium salts) and their discharge into the lumen of the intestine, from where the excretory products are passed with the feces. Strict water resorption usually occurs at the base of the Malpighian tubules and in the rectum, avoiding the waste of water.

Nervous System

The nervous system of insects mainly consists of a rather thick rope ladder-like ventral chord with a pair of ganglia within each segment. In several insect groups this rope-ladder becomes, however, condensed to a rather thick chord. The “brain” (i.e., cerebral ganglion) is comprised of the enlarged supra = epiesophageal ganglion (Figs. 5 and 7b), which is connected by connectives with the subesophageal ganglion, which has been formed due to the fusion of the ganglia of the mouthparts. The epiesophageal ganglion is subdivided into 3 regions:

- The protocerebrum is rather large; it innervates the compound eyes with large lobi optici and functions as center of associations.
- The smaller deutocerebrum innervates the antennae, which are equipped with numerous sensillae.
- The tritocerebrum forms a commissure running below the intestine.

The rather large ganglia pairs of the pro-, meso-, and metasomal segments innervate the 3 pairs of legs and – if present – the muscles of the wings. In the abdomen 7 pairs of ganglia are present. Ring nerves to steer the different body organs initiate from these sites.

The additional visceral (i.e., vegetative) nerve system consists of 3 regions:

- The stomatogastric part, which innervates the mouth and anterior intestine comprising

frontal, hypocerebral and ventricular ganglia, the ► [corpora cardiaca](#), and the ► [corpora allata](#).

- A singular ventral nerve chord which innervates the stigmata.
- The caudal system which is responsible for the intestine and the gonads.

The whole nervous system of insects is 5,000 times more sensible to insecticides of the recently used pyrethrum/pyrethroid family than that of vertebrates – a fact which is used to control pests and bloodsucking insects (Ectoparasitocides, ► [Arthropodicidal Drugs](#)).

Instar

A stage in the life of an arthropod between 2 successive molts, e.g., in ► [Ticks](#) and ► [Insects](#).

Insulin

General Information

Insulin is a phylogenetically old peptide hormone, being present at least in molluscs, insects, and vertebrates. Its functions are related to regulation of ► [energy metabolism](#) and growth.

Pathology

Hypoglycaemia is a major complication of severe ► [malaria](#), especially in cerebral malaria where it is associated with increased mortality. In uncomplicated falciparum malaria, glucose production is increased by about 25 %, due to an increase in gluconeogenesis and a simultaneous decrease in glycogenolysis, but hypoglycaemia is mainly caused by hyperinsulinaemia. If insulin secretion

is blocked, hypoglycaemia can be reversed. Glycophosphatidyl inositol membrane anchors of malaria proteins are released as malaria toxic antigens and act synergistically to insulin. They induce production and release of tumour necrosis factor from macrophages, they stimulate lipogenesis and inhibit lipolysis in adipocytes.

Implications

Monoclonal antibodies against the glycophosphatidyl inositol of parasite origin can neutralize the toxic effects of parasite extracts.

Integrated Pest Management

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes the simultaneous use (ITP) of a bunch of different methods to control overflooding specimens of a given insect species in a limited area. This action may include at the same time use of chemical compounds, methods of ► [sterile male technique](#), and/or setting free cultivated aggressive insects such as tephritid flies (true fruit flies), wasps, ants, and/or termites, etc., depending on the targeted invaders.

Interleukins

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Group of cytokines, which are essential elements of the immune system:

Interleukin-2 (IL-2)	It is an essential mitogen and T-cell growth factor.
Interleukin-6 (IL-6)	This acts as inflammatory cytokine and pyrogen promoting IL-17 expression by T-cells, B-cell activation, and activity of phagocytes
Interleukin-10 (IL-10)	This is a regulatory cytokine that suppresses APC activation, which reduces indirectly potent T-cell responses
Interleukin-17 (IL-17)	This is an inflammatory cytokine promoting activation and differentiation of phagocytes and neutrophils
Interleukin-27 (IL-27)	This is a regulatory cytokine suppressing the activation and proliferation of the IL-17, expressing T-cells but promoting the formation of IL-10-expressing T-cells

Intraconoidal Microtubules

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Motile stages of some Apicomplexa (e.g., merozoites, sporozoites, tachyzoites, bradyzoites, cystozoites) possess a protrudable ► [conoid](#), which possesses two preconoidal rings, but it is always absent in similar stages of the genera ► [Plasmodium](#), ► [Theileria](#), and ► [Babesia](#). Besides the ductules of the ► [rhoptries](#) two single (conoidal) microtubules pass the inner of the conoid reaching until the apical cell membrane. Their function is not yet understood. It might be that they are phylogenetic remnants, since they have also been proven recently in non-apicomplexan protozoans such as the photoautotrophic species *Chromera velia* (lives in coral banks). This flagellated species has also a conoid, which, however, is open along the side (proximal to a groove) of the protruding flagellum.

Invasion

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Latin: *invasion* = penetration.

Penetration of a parasite or of another agent of disease into an organism, an organ, or into a cell.

► [Apicomplexa](#).

Iodamoeba buetschlii

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This amoeba (syn. *Jodamoeba buetschlii*, *J. williamsi*) lives as commensal in the human intestine and has in its cyst stage (6–15 µm) a very large vacuole-containing glycogen. The single nucleus contains a large nucleolus, but has no peripheral densification. The amoeboid stage, which measures 10–20 µm, may form two pseudopodia at the same time. This species was described by von Prowazek in the year 1912 and occurs mainly in the colon of monkeys, pigs and rats.

Iodofenphos

Chemical Class

Organophosphorous compounds
(monothiophosphate).

Mode of Action

Isospora belli

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

1. **Name:** Greek: *isos* = similar, identical; *sporos* = spore; *kystos* = cyst; Latin: *bellum* = belly.

2. **Geographic Distribution/Epidemiology:** Worldwide occurrence; several 100 millions infected people, not occurring as true epidemics.
3. **Morphology/Life Cycle:** This organism belongs to the so-called ► [Coccidia](#), which are members of the former phylum Sporozoa/Apicomplexa in the newly created ► [Alveolata](#). It parasitizes intracellularly the epithelial cells of the intestine of humans being situated inside a ► [parasitophorous vacuole](#). Infection of humans occurs by oral uptake of oocysts of the *Isospora* type from remnants of human feces. The oocysts, which appear ovoid with a flattened pole (Figs. 1 and 3), are excreted non-sporulated. Outside of the host's body, two sporocysts are developed within 2–3 days inside the oocyst finally containing each four sporozoites, which are the infectious stages after oral uptake of the oocyst by another human being (Figs. 2 and 3). These oocysts measure $25\text{--}35 \times 18\text{--}20 \mu\text{m}$ and keep their infectivity for at least 1 year, even when temperatures are low or even close to the freezing point.
4. **Symptoms of Disease:** Oral uptake of these oocysts within contaminated food or drinking water leads to diarrhea called either coccidiosis, isosporiasis, or more common traveler's disease. In many cases there occur very quickly (about 2 days after the infection) severe symptoms of disease: repeated diarrheas combined with strong abdominal pain, nausea, and vomiting which persist for several days or even weeks. On the other hand, other persons excrete oocysts without significant symptoms and may infect whole groups of persons (e.g., during common excursions in nature). AIDS patients are especially endangered, since these parasites do not only attack the intestinal cells but are also found in masses intra- and extracellularly in lymph nodes far from the intestine. In AIDS patients in addition to the increased diarrheas, other symptoms occur additionally: malabsorption and steatorrhea (Restrepo et al. 1987). In AIDS patients as well as in

***Isospora belli*,**

Fig. 1 Light micrograph of an unsporulated oocyst of *Isospora belli*

***Isospora belli*,**

Fig. 2 Light micrograph of a sporulated oocyst of *Isospora belli* showing inside two globular sporocysts within which four sporozoites are finally formed

immunocompetent travelers, diarrheas due to these parasites may start again 2–20 weeks after the excretion of oocysts and symptoms had stopped due to a successful treatment (relapse with unknown reason).

5. **Diagnosis:** The oocysts can easily be diagnosed by microscopic investigation after the use of concentration methods: ► [M.I.F.C.](#), ► [S.A.F.C.](#), ► [flotation](#). At first the oocysts are unsporulated (Figs. 1 and 3), but within 2–3

***Isospora belli*,**

Fig. 3 Diagrammatic representations of an unsporulated (a) and a sporulated and thus infectious (b) oocyst of *I. belli*. *N* nucleus, *OW* oocyst wall, *R* residual body, *SP* sporozoite, *SW* sporocyst wall, arrow points at an apical flattening

days, two sporocysts each with four sporozoites have developed (Figs. 2). In biopsy material of the intestinal wall, also schizonts, merozoites, and gametocytes can be found, but their structure is not species specific. In some cases, the blood status shows a mild eosinophilia.

6. **Infection:** Oral uptake of sporulated oocysts (Figs. 2) within contaminated food or drinking water.
7. **Incubation Period:** 2–13 days, when the production of schizonts inside the intestine occurs and may lead to first symptoms.
8. **Prepatency:** 7–9 days.
9. **Patency:** 2 weeks up to 1–2 years (in AIDS patients).
10. **Therapy:** The acute isosporiasis (traveler's disease) is often self-limiting in case the patient ingests enough drinking water. However, in severe cases and under chronically repeated outbreaks (especially in the case of immunocompromised persons), the following cure is effective: cotrimoxazole (4 × 800 sulfamethoxazole and 160 mg trimethoprim daily for 10 days followed by twice daily for 3 weeks). Pyrimethamine (50–75 mg daily) acts as well. Rezidive prophylaxis can be done (1 × 40 mg sulfamethoxazole and 80 mg trimethoprim daily). In the USA, patients were successfully cured by

application of diclazuril (1 × daily 200 mg for 7 days). Also ciprofloxacin (2 × daily 500 mg for 7 days) limits the number of parasites.

Isospora Species of Animals

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *isos* = identical; *sporos* = seed, spore; *kystis* = cyst, capsule.

Geographic Distributions/Epidemiology

The isospores are worldwide found as parasites of many groups of vertebrates. Their abundance in single infected hosts may reach very high numbers, as well as the rate of infection among given host population may reach 90 %.

Isospora Species of Animals, Fig. 1 Two unsporulated oocysts of the genus *Isospora* (light micrograph)

Morphology/Life Cycle

In the present overlook only a few species are considered out of a number of several hundreds. The life cycle has the same phases (schizogony, gamagony, sporogony) like the ► *Eimeria* species, which are as numerous. The difference is that in *Isospora* species the oocysts include two sporocysts with four sporozoites (Fig. 1), while in oocysts of *Eimeria* species four sporocysts with two sporozoites occur (► *Coccidia*). The oocysts are excreted in an unsporulated state and form their infectious stages in species-specific and temperature-dependent times outside of the host (=sporulation). Due to the extremely resistant oocyst wall the parasites inside can survive extreme conditions for years. Some examples of important *Isospora* species are listed in Table 1.

Symptoms of Disease

Slight infections remain mostly symptomless. However, especially young animals suffer from diarrhea, which may be fatal due to huge loss of water. However, after surviving such an infection immunity protects them further on.

Diagnosis

Isolation of oocysts (Figs. 1 and 2) by concentration methods (► *S.A.F.C.* M.I.F.G., ► *flotation*) from feces shows the species specific oocysts

Isospora Species of Animals, Table 1 Important *Isospora* species of animals

Species	Host/Habitat	Size of oocysts (µm)	Prepatent period	Pathogenicity
<i>I. suis</i>	Pigs/Small intestine	17–22 × 17–19	5–6	+
<i>I. canaria</i>	Canaries/Intestine	13 × 10	4–5	–/+
<i>I. erinacei</i>	Hedgehogs/Small intestine	28–34 × 23–27	7–14	+
<i>I. farahi</i>	Lizards/Intestine	29 × 28	6–8	+
<i>I. lacazei</i>	Sparrows/Intestine	22–35	7–8	–
<i>I. lacerate</i>	Lizards/Intestine	28 × 26	5–7	+
<i>I. serini</i>	Canaries/Intestine and its wall, liver, lung	12 × 10	9–10	+

Isospora Species of Animals, Fig. 2 Sporulated oocyst of the genus *Isospora* containing two sporocysts each with four sporozoites (light micrograph)

(compare Figs. 1 and 2 in ► *Cystoisospora* species). The size and details of some species are listed in Table 1.

Infection

Oral uptake of sporulated oocysts with fecally contaminated food.

Prophylaxis

Quick removal of animal feces from breeding sites.

Incubation Period

High variations in the different species: a few days until weeks.

Prepatent Period

Examples see Table 1.

Patency

Species specific: 1 to several weeks.

Therapy

The medicament of choice is toltrazuril (10 mg/kg bodyweight) orally for 4–5 days.

Isospora suis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *isos* = identical; *sporos* = seed, capsule.
Latin: *sus* = pig, boar.

Geographic Distributions/Epidemiology

Worldwide; in the case of piglets, eventually epidemics involve up to 80 % of the animals in a farm. Due to the short prepatent period of 5 days and the extremely quick sporulation of the oocysts within 15 h at high temperatures, a quick progress of the epidemic occurs in stables.

Morphology/Life Cycle

The oocysts ($17\text{--}22\ \mu\text{m} \times 17\text{--}19\ \mu\text{m}$) appear colorless pale. The development (schizogony until formation of oocysts) occurs in the epithelial cells of the jejunum and ileum of pigs.

Symptoms of Disease

Catarrhalic enteritis (often with lysis of the epithelium layer) resulting in villous atrophy occurs within 9 days after infection. This all together results in a non-hemorrhagic diarrhea with subsequent reduced nutrient absorption, leading to weight loss and stunted growth. High general morbidity or even death of very young piglets may occur.

Diagnosis

Microscopical evaluation of typical isosporan oocysts ($17\text{--}22\ \mu\text{m} \times 17\text{--}19\ \mu\text{m}$) by the help of ► [concentration methods](#).

Infection

Oral uptake of fecally excreted oocysts after they had developed sporocysts.

Prophylaxis

Quick removal of feces from pig stables and cleaning floors with hot steam.

Incubation Period

3–5 days.

Prepatent Period

5–7 days.

Patency

7–16 days.

Therapy

20 mg/kg bodyweight toltrazuril.

Isosporosis, Man

► *Isospora belli* undergoes a classical coccidian cycle with ► [schizogony](#) and

Isosporosis, Man, Fig. 1 LM of an unsporulated oocyst of *Isospora belli*

Isosporosis, Man, Fig. 2 LM of a sporulated oocyst of *Isospora belli*

gametogony mainly in the small intestinal epithelium. Unsporulated oocysts 20–32 μm in size and containing 2 sporoblasts are shed in the stools. In addition, individual encysted zoites are found in the lamina propria and mesenteric lymph nodes (► [Pathology](#), Fig. 5c). These are similar to those that occur in cats and in rodents, which can serve as the intermediate hosts of feline ► *Isospora*, which has been reclassified as *Cystoisospora felis* and *Cystoisospora rivolta*. The presence of unizoid cysts suggests that the human *I. belli* may also be heteroxenous, and may better be classified as *C. belli*. There is an intense inflammatory reaction in the lamina propria involving plasma cells, lymphocytes, neutrophils, and eosinophilic granulocytes. With ► [chronic infection](#) there is villar atrophy. Intermittent diarrhea, malabsorption, and sometimes fever.

Main clinical symptoms: ► [Diarrhoea](#), ► [vomiting](#), loss of weight.

Incubation period: 2–13 days.

Prepatent period: 7–9 days.

Patent period: 2 weeks to 1–2 months (in case of ► [AIDS](#) patients).

Diagnosis: Microscopic determination of oocysts in fecal samples (Figs. 1 and 2).

Prophylaxis: Avoid contact with human feces.

Therapy: Treatment see ► [Coccidiocidal Drugs](#).

Isthmus

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *isthmus* = constriction. This term describes the constriction of the esophagus of the first and second larvae of some nematodes (e.g., *Necator*, *Ancylostoma*, ► [Strongyloides](#)), which disappears after the molt to the infectious larva 3.

Itch

Reaction due to bites of blood suckers. ► [Mites](#), ► [Insects](#).

ITS

Internal transcribed spacer.

Ivermectin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Chemical Class

Macrocyclic lactone (16-membered macrocyclic lactone, avermectins).

Mode of Action

Glutamate-gated chloride channel modulator. Nematocidal Drugs, ► [Ectoparasitocides: Antagonists and Modulators of Chloride Channels](#).

Ivermectin application increases the release of GABA (γ -aminobutyric acid) at the presynaptic nerve ending leading to the opening of the chloride ion channels and thus increasing the GABA binding at the motor neuron.

Ixodes arboricola

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This so-called tree-hole tick is an endophilic parasite mainly found in nests of birds such as great and blue tits (*Parus major*, *Cyanistes hypoleuca*) and nuthatches (*Sitta europaea*).

Further Reading

Van Oosten AR et al (2014) Host specificity of a bird-specialized endophilic ectoparasite: *Ixodes arboricola*. Parasitol Res 113:4397–4405

Ixodes scapularis

North American ixodid tick, the genome of which was first sequenced. This black-legged tick is widespread in Southeastern USA and along the East Coast. It is a vector of tick-borreliosis, too. However, the prevalence rate of *B. burgdorferi* bacteria inside is lower than in *I. dammini* (~30 % in USA), 2 % in *I. pacificus* (West Coast of USA), or in *I. ricinus* (~30 % in Central Europe).

Ixodes Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *ixos* = clue, *ixodes* = clueing; Latin: *ricinus* = oil of a plant.

Ixodes Species, Table 1 Important Ixodes species found on humans

Species	Length (mm) of unfed adults ^a	Hosts during development	Main hosts ^b	Disease (pathogens) ^c	Type of bite-transmitted pathogens ^c

<i>I. dammini</i> ^d		3	Deer, cattle,	Borreliosis	B
<i>I. pacificus</i>		3	Humans	Encephalitis,	V
<i>I. scapularis</i>		3	Humans	Babesiosis	P

^aSize of feed ticks in brackets

^bHosts were selected according to important diseases; other hosts are possible

^cThese pathogens do not occur in all hosts and may be transmitted by other tick species, too

^dSome authors claim that *I dammini* is *I scapularis*, *B* bacteria, *P* protozoa, *V* virus, *m* male, *f* female

***Ixodes* Species, Fig. 1** Life cycle of *Ixodes ricinus* (as an example of a three-host tick, a-c). 1 Engorged females (4c) reaching a length of up to 1.5 cm drop down to the soil and over a period of 1 month they lay about 2,000 spherical to ovoid eggs which become attached to each other and thus appear as clusters on the soil. 2 6-legged larvae hatch from the eggs after 3–36 weeks (depending on the temperature) and creep onto the tops of grass blades, from where they attach to passing hosts (mostly small mammals, but also birds and humans; (a) 3 Fed larvae drop to the soil, and

molt within 5–7 weeks (sometimes up to 5 months) to become 8-legged nymphs which at this point have no genital opening. Nymphs attack larger mammals and many other hosts (b), suck blood for 4–7 days and drop to the soil, where they molt within 2–8 months and become sexually mature adults (4a = male, 4b = unengorged female). Mostly in spring the adults attack larger mammals including humans (c), where especially females suck for 5–14 days. The whole development is temperature-dependent and requires about 2–3 years in Europe

Ixodin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Anticoagulans in the saliva of ixodid ticks
(► [Ixodes](#)), which blocks the prothrombin activation of the host.

Ixodiphagus

Genus of ichneumonid wasps, the larvae of which specialize in parasitizing and killing ticks.

J

Japanese B Encephalitis

► *Arbovirus* disease in humans being transmitted during the bite of ceratopogonid ► *Diptera* (e.g., *Forcipomyia taiwana*).

Jasgur

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Russian scientist who described ► *Cheyletiella yasguri* = a mite in the hair of dogs.

Jasmolin

Chemical Class

Natural products (terpenoid).

Mode of Action

Open state voltage gated sodium channel blocker.
► *Ectoparasitocides: Blockers/Modulators of Voltage-Gated Sodium Channels*.

Jaundice

The skin and/or eyes of people infected with ► *Babesia* spp. or with obstructive liver flukes appear yellow due to disintegration of blood cells.

Jaws

Mouthparts that may occur in the anterior sucker of ► *leeches* (► *Hirudo medicinalis*) and are used to cut the skin of man and animals. They contain the excretion pores of the unicellular salivary glands.

Jigger

Synonyms

Tunga penetrans, sand flea, fleas.

Jirovec, Otto (1907–1972)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Czechoslovakian microbiologist who described together with his colleague Vanek that a separate

human species of *Pneumocystis* exists (later by Frenkel called *Pneumocystis jirovecii*), which is different from *P. carinii*, which was believed to exist in humans and rodents.

Joyeuxiella

Genus of tapeworms belonging to the family Dipylidiidae (► *Dipylidium caninum*). Species of the genera *Joyeuxiella* and *Diplopylidium* are described to have coprophagous beetles as first intermediate hosts. In addition, small mammals and/or lizards are active as transport hosts.

Joyeuxiella Species

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This tapeworm genus contains species (e.g., *J. pasqualei*, *J. chyzeri*) parasitizing in dogs, cats, and wild carnivores, which have a similar life cycle like that of *Dipylidium caninum*. These species belong to the group of Cyclophyllidea (Dilepididae). Their scolex is provided with 4 suckers and a protrudable cylindric rostellum, which bears thorn-like hooks. Intermediate hosts are coprophagous beetles and eventually reptiles (as transport hosts). The excreted egg packages contain only a single egg instead of the 8–30 eggs which occur in egg packages of *Dipylidium caninum*. *Joyeuxiella* worms are worldwide distributed in countries with warm temperatures. The proglottids of these species contain two sets of sexual organs (Fig. 1). The terminal proglottids are filled with a saclike structure containing the egg packages (Fig. 2).

Joyeuxiella Species, Fig. 1 Light micrograph of the central strobila of *Joyeuxiella pasqualei* showing the double mature sexual organs (Prof. Dr. Schuster, Dubai)

Joyeuxiella Species, Fig. 2 Light micrograph of terminal proglottids of *J. pasqualei* (Prof. Dr. Schuster, Dubai)

Juvenile Hormones

Synonyms

Methyl farnesoates (MF).

General Information

A unique feature of insect and crustacean endocrinology is the presence of a class of hormones with a dihomosesquiterpenoid skeleton, the so-called juvenile hormones (JH), resp. methyl farnesoates (MF). These are lipophilic compounds that are degraded by specific (JH-epoxid-hydrolase, JH-esterase) and unspecific (esterases) enzymes. As in ► [ecdysteroids](#), there exist congeneric hormones, JH 0 to JH III (Fig. 1), but in contrast to ► [ecdysteroids](#), JH and MF are synthesised by the insects and crustaceans themselves. The synthesis, metabolism, titre regulation, transport, and physiological functions of this class of hormones is summarised in recent reviews. The distribution of juvenile hormones in other animal taxa has been investigated much less than that of ecdysteroids. There are reports on the presence of juvenile hormone activity in other invertebrates, but these reports are questionable for methodological reasons.

Methyl farnesoate

(10R) - Juvenile hormone III

Juvenile Hormones, Fig. 1 Juvenile hormone. Structure of 1 juvenile hormone from an insect and the corresponding crustacean representative methyl farnesoate. Molecular weights: 263 (JH I), 247 (MF)

Physiological Function

Juvenile hormones not only exert juvenoid actions (that means that the larval character is maintained and further development to the adult inhibited) but they also function as gonadotropic hormones during adulthood.

Implications

Because of the unique structure of juvenile hormones and their function during different developmental stages, these compounds as well as their antagonists are well suited as insect growth regulators and have been successfully applied in pest control. They also affect ► [nematodes](#) although the mode of action in this systematic group is completely unknown. There are neither unequivocal proofs for the existence nor for a putative function of juvenile hormones in this taxon.

K

Kairomones

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und

Name

Kalabar = Calabar, Nigerian town at the coast of
the Gulf of Guinea.

► [Filariidae](#), clinical symptom due to infection
with ► [Loa loa](#).

Karakurte

Black widow spider (= *Latrodectus mactans*).

Karyogamy

From Greek: *karyon* = nucleus, *gamein* = fuse.
Process of fusion of the nuclei of mating gametes.

Karyolysus lacertae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Classification

Species of Coccidia, phylum Alveolata.

Life Cycle

See Fig. [1](#).

Karyolysus lacertae, Fig. 1 Life cycle of *Karyolysus lacertae* inside its hosts, the lizard (*Lacerta muralis*) and the blood-sucking mite (*Liponyssus saurorum*). 1 Lizards become infected when they swallow mites containing sporozoites. 2–5 The sporozoites penetrate the gut epithelium and invade the endothelial cells of blood capillaries. After repeated formation of differently shaped schizonts and merozoites, the last generation of merozoites enters erythrocytes, where they grow into gamonts (5). 6–8 The gamonts are ingested by the blood-sucking female mite and are released into the gut during digestion; they associate in pairs, forming an elongated, spindle-shaped “syzgy.” In this shape the pairs of gamonts are engulfed by the gut cells of the mite. 9–12 Once inside the host cell the macrogamont increases in size. The nucleus of the

microgamont divides once and finally produces two flagellated microgametes (11; MG). One microgamete fertilizes the macrogamete, which grows considerably as a zygote (12). 13–16 After nuclear divisions (13, 14) motile sporokinets (up to 50 µm long) are formed, which leave the gut epithelium for the body cavity (16) and may enter the ovary and finally the egg. 17–19 Inside the ► **yolk** cells of the mite’s egg and later in the cells of the larva and nymphs, each ► **sporoblast** gives rise to 20–30 infectious sporozoites by an asexual, intracellular reproduction. Typical oocysts or sporocysts do not occur. DG degenerating host nucleus, E erythrocyte, EG egg of the mite, HC host cell, MG microgamete, N nucleus, NH nucleus of host cell, PV ► **parasitophorous vacuole** (for further species see ► **Coccidia**/Table 6)

Karyosome

Former name of ► [nucleolus](#). ► *Entamoeba histolytica*.

Kerteszia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Subgenus of ► *Anopheles* mosquitoes.

Khawia

Genus of the basic cestode family Caryophyllidae. *K. sinensis* is found in cyprinid fish. It has only one set of sexual organs, reaches a length of about 5–10 cm, and lives in the upper intestine. The scolex is folded and thus often compared to a flower; the body does not show segmentation. Intermediate hosts are annelids (*Tubifex*), which feed the 75 µm sized eggs. The development in the final host fish is temperature-dependent and takes 2 weeks up to 6 months.

Therapy

Tremazol™ (Sera/Alpha-Biocrine).

Kidney Worm

Synonyms

Stephanurus dentatus, *Dioctophyme renale*.

Killigrewia

Synonyms

Aporina.

Classification

Genus of tapeworms.

K. delafondi reaches a length of 23 cm and a width of 4.5 mm in the small intestine of doves and other birds; oribatid mites are claimed as intermediate hosts.

Kinete

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In the protozoan genera ► *Plasmodium* (e.g., agents of ► *malaria*), ► *Babesia*, and ► *Theileria*, the ► *zygote* (Gametes) develops into a motile stage (Figs. 1 and 3) that is able to leave the intestine of the vectors (► *mosquitoes* or ► *ticks*). In ► *Plasmodium*, the whole spherical zygote stretches and becomes a slender so-called ► *ookinete*. In ► *piroplasmids*, the kinetes (Fig. 2) develop inside a vacuole of the zygote (Fig. 1). Both kinetes and ookinetes (more correct would be ► *zygotokinetes*) are diploid and start early with meiotic nuclear divisions (Figs. 3, 4, 5, 6, and 7, p. 682, 683).

Kinetoplast

The ► **Kinetoplastida** (e.g., species of ► *Trypanosoma* and ► *Leishmania*) have a single, large mitochondrion that contains some extra DNA. These organisms have 5 % of their DNA in a single structure called the kinetoplast (► *Blastocrithidia triatomae*, Fig. 2a, ► **Mitochondria**, Fig. 1a, ► *Trypanosoma*, Fig. 5b) which is located close to the basal body of the flagellum. Kinetoplastid flagellates have no infoldings of the inner membrane in this region of the ► **mitochondria**, providing space for the thousands of minicircles (0.3–0.8 µm in length) and the few maxicircles (9–11 µm in length) that make up their mitochondrial DNA; this region stains with Giemsa solution and is visible as a

deep purple dot (formerly also called ► **blepharoplast**). During cell division the kinetoplast is always reproduced before ► **nuclear division** occurs.

Kinetoplast DNA

Kinetoplast DNA (kDNA), the first extranuclear DNA to be discovered in eukaryotes, is a distinguishing feature of all kinetoplastid species. Within the cell, the kDNA is composed of a giant network of catenated, circular DNA molecules condensed into a disc-shaped structure that is localized in the part of the single mitochondrion adjacent to the flagellar basal body. This DNA represents 5–25 % of the total cell DNA mass and consists of about 50 (23–36 kb, depending on the species) maxicircles and several thousand (5,000–10,000 copies per cell) of 0.5–2.5 kb minicircles. In addition, various proteins are associated with the kDNA that are suggested to be involved in the organization and segregation of the network. Maxicircle DNA is homogeneous in sequence and contains transcriptionally active genes that correspond to those of other ► **mitochondria**. Maxicircle transcripts are cryptic and require editing to form functional mRNAs. The 20 identified genes in maxicircle DNA of *Trypanosoma brucei* encode 2 ribosomal RNAs, 2 small RNAs, termed ► **guide RNAs** (gRNAs), and 18 proteins with homology to NADH dehydrogenase, apocytochrome *b*, cytochrome *c* oxidase subunits I, II, and III, and a subunit of mitochondrial ATPase. Minicircle DNA represents a unique form of mitochondrial DNA not only because of its small size and large numbers but also because it is responsible for the kDNA complex network structure. They are usually heterogeneous in sequence but identical in size within a network. Minicircles encode gRNAs that control ► **RNA editing** specificity within the kinetoplastid mitochondrion. In *T. brucei*, each minicircle encodes 3–5 gRNAs, whereas *Leishmania tarentolae* encodes only a single gRNA per minicircle. The replication of kDNA occurs

during nuclear S phase and includes the duplication of free detached minicircles and catenated maxicircles followed by the generation of two daughter kDNA networks that segregate upon cell division.

Kinetoplastid RNA (kRNA)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The editing activity of kinetoplastid RNA (kRNA) is discussed to be steered as follows (Hashimi et al. 2012).

Guide RNAs (gRNAs) deliver a blueprint for the uridine insertion respectively deletion into/from mitochondrial RNAs by the RNA editing core complex (RECC). This process is supported by the RNA-binding complex (MRBB1), which mediates multi-round kRNA editing by coordinating the exchange of multiple gRNA required by RECC in order to be able to edit lengthy regions of mRNAs and then to link kRNA editing with other RNA processing events.

Kinetoplastida

Classification

Order of ► [Flagellata](#).

General Information

The Kinetoplastida were named for the presence of a Feulgen-positive ► [kinetoplast](#) which is a distinct region of the single, long mitochondrion containing coiled DNA filaments (► [Cell Multiplication](#), Fig. 2). The ► [kinetoplast](#) is always closely associated with the basal body of the flagellum. The species of the Kinetoplastida are heterotrophic and feed as saprozoic or parasitic organisms. In general, they have 1 (► [Trypanosoma](#), Fig. 1) or 2 ► [Flagella](#) (► [Trypanoplasma](#), Fig. 1) which arise from a depression of their surface (► [Flagellar Pocket](#)) and include a ► [paraxial rod](#) in addition to the ► [axoneme](#). Characteristic of some groups of the Kinetoplastida is their facultative or obligate assumption of different shapes (Polymorphism), so that they may appear as ► [amastigotes](#) (= Micromastigotes), pro-, epi- or ► [trypomastigotes](#). Reproduction occurs by an asexual longitudinal ► [binary fission](#); recently, sexual processes were described in cloned strains, indicating that at least a fusion of nuclear material must occur (Gametes). Transmission of the endoparasites belonging to this group mainly occurs via active vectors; cysts, if present at all, are rare (► [Blastocrithidia triatoma](#), Fig. 1) and are usually an additional means of propagation.

System

- Order: Kinetoplastida
- Suborder: Bodonina (with 2 ► [flagella](#))
 - Family: Bodonidae
 - Family: Cryptobiidae (parasites of fish, snails)
 - Genus: ► [Trypanoplasma](#) (► [Trypanoplasma](#), Fig. 1)
 - Genus: *Cryptobia*
- Suborder: Trypanosomatina (with a single flagellum)
 - Family: ► [Trypanosomatidae](#)
 - Genus: *Leptomonas*
 - Genus: ► [Leishmania](#) (► [Leishmania](#), Fig. 1)
 - Genus: *Phytomonas*
 - Genus: *Crithidia*
 - Genus: *Blastocrithidia* (► [Blastocrithidia triatoma](#), Fig. 1)

- Genus: *Herpetomonas*
- Genus: [▶ Trypanosoma](#)
(▶ [Trypanosoma](#), Figs. 1, 2)
 - Stercoraria (fecally transmitted by vectors),
 - Salivaria (transmitted by saliva and/or feeding organs of the vectors)

Host Cell Recognition

In *Trypanosoma cruzi*, glycoproteins have been shown to be involved in the interaction, and lectins or sugars could interfere with the phenomenon. Fibronectin, a high molecular weight glycoprotein present in blood, connective tissue, and at cell surfaces, has also been suggested to mediate interaction between trypomastigotes and host cells *in vitro*, and a fibronectin receptor of 85 kDa has been identified on the surface of trypomastigotes. The fibronectin molecule thus seems to act as a bridge between host and parasite preceding internalization.

Sialic acids which bind the surface transsialidase are needed for invasion, together with sulfated glycosaminoglycans that bind the parasite surface molecule named penetrin.

▶ [Leishmania](#) spp. ▶ [promastigotes](#) have been shown to activate complement and to bind C1 and C3, which enhances their phagocytosis by macrophages via the C1 and C3 receptors of the cells, the surface glycoprotein GP63 being one of the parasite ligands involved in the binding.

Kinines

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kinein* = moving

This term describes tissue hormones (pharmacologically active oligopeptides).

Kissing Bugs

Günter Schaub

Fakultät für Biologie, AG Zoologie/Parasitologie, Ruhr-Universität Bochum, Bochum, Germany

Synonyms

Triatominae.

Classification

Subfamily of ▶ [Rhynchotha](#). ▶ [Hemiptera](#),
▶ [Bugs](#).

General Information

The Triatominae belong to the order Hemiptera, of which fossil specimens are about 250 million years old. Of the about 80,000 recent species of Hemiptera, the majority does not suck blood, but sucks on plants, or they are predators of insects and other invertebrates. Only species of the 2 families ▶ [Cimicidae](#) (bedbugs) and Polctenidae are all bloodsuckers, and in the family ▶ [Reduviidae](#) only those 119 species belonging to the subfamily Triatominae (kissing bugs). The name of the latter group reflects a behavior of these ▶ [bugs](#), often sucking blood in the face which is unprotected at night during sleep. The majority of triatomines lives sylvatically, some peridomestically around the house, and only some species mainly domestically; of these ▶ [Triatoma infestans](#), [Rhodnius prolixus](#), ▶ [Panstrongylus megistus](#), and [Triatoma dimidiata](#) are the most important species. Triatomines are important vectors, transmitting *Trypanosoma cruzi*, the causative agent of ▶ [Chagas' disease](#), [Man](#). This is the only important tropical disease in which the parasite was first detected in the vector, then in a cat and a little girl, and then Carlos Chagas recognized symptoms of the disease. Chagas disease is mainly a disease of the poor people, because poor housing conditions,

e.g., houses made of a wooden frame covered with mud and a roof of palm leaves, offer optimal hiding places in the cracks and crevices of the wall or in the roof for the nocturnal bugs.

Triatomines are hemimetabolous insects and all nymphal stages and adults suck blood. The length of adults varies between 0.5 and 4.5 cm in the different species. Triatomines can easily be distinguished from other bloodsucking insects by a hemipteran characteristic: anteriorly the forewings are strongly sclerotized, whereas the posterior part is membranous. The membranous hindwings are folded beneath the forewings, which are closed flatly over the abdomen. In addition, triatomines possess sucking mouthparts which are reflexed under the head in rest, just barely reaching the first pair of legs. In contrast to the other hemipteran bloodsuckers, they possess a neck, clearly separating head and thorax. Rooms infested by triatomines and also Cimicidae have a special smell.

Distribution

Nearly all triatomines occur only on the American continent, from latitude 46° S to 42° N, the majority occurring in Latin America. Exceptions are some species on the Indian subcontinent and Southeast Asia, and one species, *Triatoma rubrofasciata*, which is associated with rats and thereby cosmopolitan, occurring in parts of the tropical and subtropical regions.

Morphology

The slender head laterally has large compound eyes, in adults additionally a pair of ocelli just behind the eyes. The long, thin antennae (4 segments) bear the temperature and carbon dioxide sensory organs. The mouthparts consist of a 3-segmented, straight labium, termed ► **proboscis** or ► **rostrum**, which forms a hollow sheath, never penetrating the skin. It protects the fine, piercing stylets, the 2 pairs of hair-like maxillae and mandibles, the latter forming the food- and also the salivary channel. Only in the proximal

region of the mouthparts a small labrum is visible. Head and thorax are clearly separated by a neck. The dorsal part of the thorax is covered by the strongly sclerotized pronotum and the triangular scutellum; in the ventral part they have a prosternal stridulatory groove which is used by the tip of the proboscis to produce sounds. Most species are black or brown, but in adults, the lateral sides of the tergites often show yellow, orange, or red bands or patches. Directly after emergence all stages are pink-colored until the ► **cuticle** sclerotizes. The long legs indicate that these insects are good runners. Adults of *Rhodnius* possess pads of setae at the legs enabling them to climb on smooth surfaces, e.g., in glass beakers. Adults of all species rarely fly. Only in one species, *Triatoma spinolai*, females are always wingless and males with or without wings. In this species the females and in *Dipetalogaster maxima* both sexes possess folded connectiva, allowing greater abdominal extensions during bloodsucking or before egg deposition. Both species inhabit extremely arid regions, the two South American fog deserts in Chile and Mexico. Males and females of triatomines can only be distinguished by the genital organs which are hidden under a round scale in males. Thereby, the tip of the male abdomen appears smoothly rounded, that of the female pointed. The habitus of the nymphs is similar to that of the adults, only wings are lacking, but in the course of the 5 nymphal instars the wing pads increase in size. Often nymphs “camouflage,” i.e., they throw fine dust particles onto their back which adhere there to the cuticle folds. Eggs possess an ► **operculum** which is forced away when the first instar nymph emerges, leaving the white egg shell.

Genetics

In colonies several species can produce interspecific hybrids, and also variously colored mutants develop, e.g., red eyes that are due to an autosomal recessive character. Hybrids between *Triatoma infestans* and *T. platensis* have been collected in the field.

Reproduction

Breeding in the laboratory is easily possible for many species of triatomines if they can feed on living hosts. In vitro feeding through membranes is also possible, but colonies do not develop if fed for years in this way.

Adults are ready to copulate about 3 days after the final emergence. Sex pheromones are known for some species. A single mating provides sufficient sperm for the eggs of a female, but they usually mate several times. Eggs develop after a blood meal, but some are also laid by starved females. Females lay 100–600 eggs. Most species lay the eggs loosely on the ground, but species which inhabit trees glue them to the substrate or to the feathers of the host.

Life Cycle

The duration of the different stages is not only temperature-dependent, but after eclosion from the egg also strongly determined by the availability and quality of blood and also by the supply with symbiotic bacteria. There seems to be a specific symbiont belonging to the group of Actinomycetes in each of the so far investigated 4 triatomine species, but development of nymphs and a reduced reproduction is also possible if the bugs do not take up the correct symbiont by coprophagy, but another Actinomycete. The symbionts colonize mainly the anterior midgut (cardia and stomach). The embryonic development usually lasts about 10–30 days (The first 4 instars are termed larvae and the fifth a nymph by mostly scientists in Central Europe, but all are termed nymphs by other scientists). In each of the instars, the nymphs require one full engorgement (or several smaller ones), in the final instar sometimes more to enable the molt to the next instar/adult. If no host is available, nymphs can starve for long periods of time, several months in colonies and, as found when determining starvation resistance under high humidity conditions, for up

to 1 year in the most resistant instar. However, it remains to be determined whether or not they develop normally after such prolonged starvation. Nymphal instars can be distinguished by size, especially of the head capsule and legs, not so much of the body. Final instars can easily be recognized by the great wing pads which are much smaller in the fourth instar and not previously recognizable. Under optimal conditions in the laboratory, adults of some species live about 1 year, but under natural conditions on average 3–6 months. The whole developmental cycle of most species lasts 5–12 months.

Transmission

Triatomines usually remain in the surroundings where they have emerged from the egg. However, if the host has left, starved adults fly. High population densities can be achieved in a house: by demolition 8,000 bugs of all stages were collected. Inside the house, highest population densities are found in the bedrooms or near the rest places of pets.

Feeding Behavior and Transmission of Disease

Triatomines are attracted to the host mainly by warmth, carbon dioxide, and odours of the host. In addition, bloodsucking bugs attract hungry bugs, e.g., by ► [ammonia](#) present in feces and urine and perhaps pheromones. Triatomines are capillary feeders on a wide range of warm-blooded hosts. Piercing of the skin is painless. Depending on the instar and the size of the species, they need 3–30 min to engorge 6–12 times their own body weight. In nymphs this is made possible by the extensibility of the abdominal cuticle, a hormone-dependent plasticization. In the capacious stomach the blood is stored and remains nearly undigested except for lipid- and carbohydrate uptake and lysis of erythrocytes.

Clotting of blood is inhibited by anticoagulants either from the salivary gland or the stomach. The hemoglobin is given in small portions into the small intestine in which digestion and absorption takes place. Before defecation, the dark remnants of blood digestion and the yellow urate spheres are stored in the rectum, presumably modified by absorption processes via the rectal pads. Since the amount of blood affects movement, triatomines rapidly excrete those compounds of the blood without nutritional value, at first mixed with the rectal remnants of blood digestion, then clear urine. Species defecating during or soon after blood ingestion are more important vectors than others defecating much later, because thereby *Trypanosoma cruzi* is deposited on the skin or mucous membranes of the host. Since the saliva causes itching, especially after repeated exposure, the induced scratching produces slight skin lesions. This may cause an infection, because the infectious stage, the metacyclic ► [trypomastigotes](#), cannot penetrate intact skin, but needs skin lesions or mucous membranes.

Interaction of Vector and Parasite

After ingestion of blood trypomastigotes of *Trypanosoma cruzi*, these transform in the stomach or the small intestine of the vector to a, sphero- and ► [epimastigotes](#). Only the 2 latter stages multiply. Nearly exclusively in the rectum the metacyclic trypomastigotes develop. Higher percentages of spheromastigotes develop during starvation periods of the vector, and for a relatively short period of 3–5 days after feeding of such long-starved bugs, many giant cells with many nuclei, kinetoplasts, and ► [flagella](#) also develop. Within an hour after feeding, metacyclogenesis is induced by factors present in the urine of the vector.

Trypanosoma cruzi is subpathogenic to triatomines, i.e., under optimal rearing conditions the vector is not affected, but starvation resistance and the capacity to inhibit the development of airborne bacteria in the intestinal tract is reduced.

Prophylaxis

Mosquito nets can protect against the usually night-active triatomines. However, they should not lay loose on the bed, but should be fixed below the mattress. Beds should be controlled before sleeping for nymphs hidden in them. A strong reduction of the number of triatomines was obtained by control campaigns.

Control

Education is included in the control campaigns to achieve better housing conditions and to avoid hiding places of triatomines inside the house. Adults and nymphs of triatomines can be killed using insecticides. To achieve permanent application, insecticides are incorporated in wall paints or in fumigant canisters. Whereas DDT was ineffective, BHC, dieldrine, propoxur and more recently pyrethroids are used (Insecticides, Ectoparasitocides). If control campaigns are interrupted or finished, the original vector or species of triatomines from the peridomestic populations rapidly colonizes the house. In addition, such long-term treatment may also induce the development of insecticide resistances. Therefore, new strategies of attack should be investigated. Theoretically very promising seems to be the introduction of transformed symbionts which produce substances that kill the flagellate but do not affect the vector.

Kitasato, Shibasaburo (1853–1931)

Heinz Mehlhorn

agents of plague, today called *Yersinia pestis*) or to the Manchuria in order to fight against the plague epidemics. In 1897 he detected together with his Japanese colleague Kiyoshi Shiga the agent of dysenteriae.

In Japan, Kitasato became famous since he established there a school of microbiologists and founded the Institute of Infectious Diseases and the Kitasato Research Institute as well as the company Terumo, where he developed the first fever thermometer. Today the famous Kitasato University in Tokyo harbors famous scientists searching for antiparasitic and antibiotic medicaments and harbors the Kitasato Museum. One big step was already done when Professor Satoshi Omura detected the anthelmintic efficacy of the so-called avermectins, which belong today to the most used anthelmintic medicaments with several billions of dollar revenue per year. This product is spent for free to control onchocerciasis in Africa and saves eyelight of millions of inhabitants (Figs. 2, 3, 4, 5, 6, and 7).

Kleine, Friedrich-Karl (1869-1951)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Friedrich-Karl Kleine was a German physician, became co-worker of Robert ▶ [Koch](#), described the developing cycle of the ▶ [Trypanosoma](#) stages inside the tsetse flies, developed the first

Kleine, Friedrich-Karl (1869-1951), Fig. 1 Kleine, Koch, and other members of the sleeping sickness expedition (1906–1907) (From left: Dr. Kudicke, Dr. Kleine,

Robert Koch, administrator Beck, Dr. Panse, Dr. Sacher, two laboratory helpers in front)

Kleine, Friedrich-Karl (1869-1951), Fig. 2 Original drawing of Kleine during the sleeping sickness expedition showing *Trypanosoma* stages

Kleine, Friedrich-Karl (1869-1951), Fig. 3 Case with glass vials containing the drug against sleeping sickness (Bayer 205, germanin (today suramin))

Kleine, Friedrich-Karl (1869-1951), Fig. 4 Advertiser for germanin

blood cultures of parasites, and became member of the so-called sleeping sickness expedition in 1906–1907 (Figs. 1 and 2).

At the beginning of 1914, the German Imperial Health Office sent Kleine to Cameroun (West Africa, formerly named Slave Coast (Côte des Esclaves)) in order to contain the sleeping sickness which was spreading there. Then he was surprised by the First World War. In the course of the fightings, the small German colonial army joined the neighboring Spanish colony of Muni in 1916.

Kleine returned to Germany in 1919, resigned from military service in the rank of chief surgeon general, and became professor and head of a

department in Berlin in 1920. In 1925 he was made department director in the Robert Koch Institute (an additional specification which the emperor had given to the Institute of Infectious Diseases in 1912). His name remains closely connected to a later work on a new remedy against the sleeping sickness that was discovered in 1916: “Bayer 205” or **germanin**, today called **suramin** (Fig. 2). During his expedition to Africa in 1921–1922, Kleine achieved results that resembled “biblical healings” with this drug, a colorless, water soluble derivate of urea. Germanin made a systematic control of this epidemic possible for the first time. B 205 contained suramin sodium and was developed by the German chemists

Wilhelm Roehl (1881–1929), Oskar Dressel, and Kothe (all at Bayer Company, Leverkusen, Germany), while the French Professor Fournau at the Paris ► [Pasteur](#) Institute produced a similar compound. Both medicaments replaced the former arsine compound ► [atoxyl](#) and the so-called trypan red of the German Nobel Prize Winner Paul ► [Ehrlich](#) (1854–1915) and his Japanese co-worker Kiyoshi ► [Shiga](#).

Suramin is still today the drug of choice in infections with ► [Trypanosoma rhodesiense](#) although it has severe side effects such as shock, urticaria, toxic effects on kidneys, etc. Similar severe side effects are also noted in more recent medicaments such as ► [eflornithine](#) and pentamidine isethionate. See trypanocidal drugs (Figs. 3 and 4; Grüntzig, Mehlhorn 2010).

Klossiella Species

Klossiella spp. (Fig. 1, e.g., *K. equi* in horses, *K. muris* in laboratory and other mice, *K. cobayae* in guinea pigs or *K. boae* in boid snakes) develop in cells of the kidneys of their hosts, lead to the formation of thin-walled oocysts with up to 60 sporocysts, and often introduce a severe disease including nephritis and haematuria. Infection occurs due to the oral uptake of

Klossiella Species, Fig. 1 Diagrammatic representation of an equine kidney endothelial cell containing an oocyst with many developing *K. equi* sporocysts (a). (b) Separated sporocysts with sporozoites. The oocysts measure 50–100 μm , which produce about 40–60 sporocysts with

a diameter of 10 μm (BM basal membrane, E developing sporozoites, EZ epithelial cell, N nucleus, NH nucleus of host cell, PV parasitophorous vacuole, RB residual body, S sporozoite, SW wall of sporocyst)

sporocysts (containing 10–15 sporozoites), which after ingestion leave the intestine, enter blood capillaries, and thus reach the kidneys. Treatment may be done by coccidiostatica.

Knemidocoptes

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of ► [mites](#), which are mange mites of birds. The males grow up to 0.25 mm, the spherical females (Fig. 1) reach a diameter of 0.5 mm.

K. mutans is found in the skin of the feet of chicken and doves and develops via one larva and two nymphs within 20 days (male), respectively, 26 days (females). *K. pilae* is mainly found in the face of psittacine birds but also occurs in the cloaca. *K. laevis* parasitizes the skin of the back of chicken and doves.

Knemidocoptes, Fig. 1 LM of the ventral side of *Knemidocoptes pilae* (Courtesy of Professor Dr. Ribbeck)

Disease

K. mutans introduces the so-called chalk-leg-mange in birds, *K. pilae* the bill-mange of birds, and *K. laevis* leads to the body-mange with the typical loss of feathers.

Therapy

Acarizides, Ectoparasitocidal Drugs.

erythrocyte surface antigen), the spectrin-dimers of the ► [cytoskeleton](#) of the host cell. At the tip of these knobs ► [adhesion proteins](#) (e.g., sequesterin) are formed which are responsible for the adhesion and rosetting of infected red blood cells, thus leading to thrombic blockade of blood vessels.

► [Malaria](#)

Knock-Down Effect

Degree of killed bloodsuckers, when attaching/getting contact to an insecticide-treated animal or surface. It is measured in percentage of killed vectors in relation to the days after treatment.

Knott's Blood Test

Method to detect microfilariae in blood of a patient. The blood is taken at species-specific hours (► [Wuchereria](#), ► [Loa loa](#)). 1–10 ml blood is diluted with 10 times more of a 2 % aqueous solution of formalin, centrifuged for 10 min at

1,500 g, and then the sediment is examined with the light microscope.

Koch, Robert (1843–1910)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

German physician (Figs. 1, 2, 3, and 4), who received 1905 the Nobel Prize in Medicine or Physiology for the discovery of the agent of

tuberculosis in the year 1882. He was the first to describe the anthrax bacterium (*Bacillus anthracis*) (1876) and the tubercle bacillus (1882) and to demonstrate in 1884 the agent of the cholera (*Vibrio cholerae*). He and his coworkers also contributed important knowledge on trypanosomiasis and to babesiosis as well as ► [theileriasis](#). He ameliorated techniques for microscopy of bacteria and made first photos of those “New World agents” being supported by the famous German microscopy developers Ernst Abbé (1840–1905) and Carl Zeiss (1810–1888). He formulated the famous still today valid postulations, which have to be fulfilled for a full description of an agent of disease:

1. The organism must be constantly present in diseased tissues.
2. The organism must be isolated.
3. The organism must be grown in pure culture.

Koch, Robert (1843–1910), Fig. 1 Robert Koch. Painting of the 46-year-old scientist just after his major discoveries and at the time of his second marriage to Hedwig Freiberg (Kitasato Museum, Tokyo)

Koch, Robert (1843–1910), Fig. 2 Photo of Koch's original smear preparation of the agents of anthrax

Koch, Robert (1843–1910), Fig. 3 Blue-colored tubercle bacilli from a lung at the stage of a miliary tuberculosis (Original drawing of R. Koch 1884)

4. The organism must induce the same symptoms of disease, when injected into an experimental animal.

He created in 1900 the famous Robert Koch Institute in Berlin, which is even today the German head center for infectious diseases. In 1905 he was awarded with the Nobel Prize in Medicine or Physiology for his breakthrough in tuberculosis research. This honor did not keep him at home, but in the years 1906–1907, Koch and his coworkers started a new expedition to Africa in order to treat native people in East Africa during an epidemic of sleeping sickness

Koch, Robert (1843–1910), Fig. 4 Robert Koch investigating at the microscope

(human trypanosomiasis) by the first chemical compound in this field (atoxyl).

He was not only a giant scientist and besides the French colleague Pasteur the “father” of bacteriology but also creator and stimulator of a large group of scientists, who all contributed breaking new knowledge in many fields of medicine (e.g., Behring, Ehrlich, Kitasato, Kleine, Löffler, Prowazek, Yersin) (Figs. 5, 6, 7, 8, and 9).

DOI 10.1007/978-3-662-43978-4

Labyrinthomorpha

Phylum of ► [Protozoa](#) that form cysts and ameba-like stages on marine organisms.

Laelaps agilis

About 2 mm long bloodsucking mite in the fur of mice (Fig. 1).

***Laelaps agilis*, Fig. 1** SEM of the ventral side of an adult; note the stiletto-like chelicerae

Laelaptidae

Family of mites, that are found on insects (e.g., genus *Myrmonyssus*), while others parasitize mammals (genera *Echinolaelaps*, *Haemolaelaps*, *Laelaps*). The larvae and nymphs are mostly lymph feeders, while the adults are hematophagous. The life cycles (including egg, larva, protonymph, deutonymph, and adults) is completed within 8–28 days. During the blood meal the blood parasite ► *Hepatozoon* may become transmitted.

Lagochilascaris

Genus of ascarid ► [nematodes](#), which occur in general in wild animals, but which may also enter (as larvae) humans leading to larva migrans interna.

Lama branchialis

Microsporidian species of freshwater fish (*Gluega*).

Lamarck, Jean Baptiste de Monet (1744–1829)

French zoologist and evolutionist; he believed in the genetic transmission of acquired qualities.

Lambl, W. D. (1824–1895)

Austrian physician, discoverer of the agents of the giardiasis.

Lamblia

Old genus name for *Giardia* spp. ► [Diplomonadida](#), ► [Giardia lamblia](#).

Lambliasis

Synonyms

Giardiasis, Man.

Landsteiner, Karl (1868–1943)

Austrian pathologist, discoverer of the human blood groups and the rhesus factor. Winner of the Nobel prize in 1930.

Langerhans Cells (LCs)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term honours the German pathologist Paul Langerhans (1847–1888) who first described the Langerhans islets (*insula pancreaticae*) inside the pancreas. Langerhans cells, however, act as macrophages inside the epidermis phagocytizing penetrated pathogens and present them to T-cells inside lymph nodes.

Lapudrine-Dapsone (Lapdap)

► [Malariacidal Drugs](#).

Large Roundworms of Ruminants

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

See ► *Toxocara vitulorum* = English trivial name for roundworms of cattle.

Larva

From Latin: *larva* = mask. Non-fertile developmental stage of helminths and arthropods (plural: larvae).

Larva Currens

Larva 3 of ► *Strongyloides stercoralis* which after penetration wanders with a high speed (20 cm/h) inside the skin of humans and leads to serpiginous pruritic eruptions.

Larva Migrans

Larvae of ► *nematodes*, which have animals as final hosts, wander through the body of humans in case they become infected.

- Larva migrans externa: For example, larva of ► *hookworms* of dogs (► *Ancylostoma caninum*) stay within the skin and lead to externally visible channels.
- Larva migrans interna: the larvae, for example, of ascarids of dogs or racoons (► *Toxocara canis*, ► *Bayliascaris procyonis*) wander through internal organs if eggs are swallowed by humans.
- Spargana: larvae of ► *tapeworms* of fish-predating birds wander as a so-called

- *sparganum* inside the body of humans if they have eaten raw fish meat containing
- *plerocercoid* larvae.

- *Cestodes*.

Larval Tapeworms

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Greek: *kystis* = bladder, cyst; *kerkos* = tail; *koinos* = together, common; *ura* = tail; Latin: *tenuis* = thin; *ovis* = sheep; *bos* = cattle; *collis* = protrusion; *multiceps* = with many heads.

Geographic Distribution/Epidemiology

Worldwide.

Morphology/Life cycle

- (a) *Cysticercus bovis*: 10 × 4.5 mm sized bladder = larval stage of the tapeworm *Taenia saginata* of humans. This stage occurs in muscles of cattle.
- (b) *Cysticercus tenuicollis*: 5–15 cm long, thin-necked larvae of the dog's tapeworm *T. hydatigena*, which is mostly situated in the omentum of its intermediate hosts (ruminants).
- (c) *Cysticercus ovis*: 10 × 5 mm sized larva of the dog's tapeworm ► *Taenia ovis* being situated often in heart, diaphragm, and masseter of intermediate hosts (e.g., sheep).
- (d) *Coenurus cerebralis*: Up to 5 cm sized translucent larva of the dog's tapeworm *Taenia*

(syn. *Multiceps*) *multiceps*; at its inner side several protoscolices are formed. This parasite is found in the brain of sheep but occasionally also in humans.

- (e) **Hydatids of *Echinococcus*:** These very large cysts contain many daughter cysts within which thousands of protoscolices are produced. This larval stage is formed due to infections with *Echinococcus granulosus*. It occurs in a broad spectrum of intermediate hosts including humans.
- (f) **Alveolar cysts:** This type of larvae, which is formed due to an infection with the tapeworm ► *Echinococcus multilocularis*, occurs mainly in rodents but also in humans. It grows tumor-like with the help of undifferentiated cells.

Diagnosis

In humans: investigations with computer tomography or MRT. In animals, these larvae are mostly only found after slaughter. Serological tests are also available.

See *Taenia* species; ► *Echinococcus* species.

Larvicidal and Repellent Effects of Essential Oils

Heinz Mehlhorn¹ and Abdelkrim Amer²

LD₅₀

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Dose of a medicament which kills 50 % of the actually present parasites.

Lecithodendriidae

Family of flukes with spined tegument parasitizing the gut of insectivorous vertebrates. However, *Phaneropsolus* sp., *Prosthodendrium* sp., or *Paralecithodendrium* also live in humans. Intermediate hosts are aquatic insects.

Leeches

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Hirudinea, from Latin: *Hirudo* = leech

Classification

Hirudinea is a subclass of ► [Annelida](#).

General Information

In general, members of the Hirudinea, which are endowed with a complete intestinal tract, look like platyhelminths and are dorsoventrally flattened monoecious animals (► [Hermaphrodites](#)). Mostly they develop 32 inner segments (except for 29 in *Acanthobdella*), which each corresponds to 2–14 outer annuli (some authors count 34 segments). Except for *Acanthobdella*, the Hirudinea, parasitic or not, are characterized by an oral sucker and a posterior disklike ► [acetabulum](#), which act as strong holdfast organs supporting movements on the surface of animal hosts, plants, etc. (Figs. 1, 2, 3, 4, and 5, ► *Hirudo medicinalis*/Figs. 1 and 2). Bloodsucking leeches produce enzymes (e.g., hirudin) preventing coagulation of blood during feeding. Typically, closed circulatory vessels and a definitive respiratory system are lacking in most

pole of the unicellular salivary gland cells, *EZ* epithelial cells, *K* jaw, *KU* cuticle, *N* nucleus, *PH* pharynx, *S* saliva, *SD* salivary gland (unicellular), *Z* tooth channel

Leeches, Fig. 5 *Hirudo medicinalis*. Location of eyes

species, and the coelom cavities are restricted to a few blood-transporting lacunae. The ontogenesis of the Hirudinea proceeds directly, without involving any larval stages (such as the ► **trochophora** larva which is characteristic for other annelids). Thus, juvenile worms hatch immediately from eggs which are joined in packs of 1–200 into a ► **cocoon**; the latter is secreted 2 days to months after copulation of two individuals by their ► **clitellum** region (segments 9–11).

System

The classification of the Hirudinea is still a matter of debate; however, the following groups are widely accepted:

Subclass: Hirudinea (some parasitic species).

Order: ► **Acanthobdellida**.

Unlike other orders, they show only the posterior ► **acetabulum**, are endowed with some surface bristles, and are composed of 29 inner segments (each with four outer annuli).

Order: ► **Rhynchobdellida**.

The anterior part of the intestine forms a large, protrusible, and retractile ► **proboscis** without teeth; specimens suck blood and thus may

transmit several endoparasites; they are eyeless, their blood is colorless, and host location occurs by body contact.

Order: ► **Gnathobdellida**.

The anterior part of the intestine is noneversible, but is armed by three pairs of ► **jaws** with varyingly strong cuticular teeth; the members of this group that are up to 25 cm long are characterized by five pairs of eyes, five annuli per segment, and red blood in a lacunar system; ► **host finding** occurs by means of olfactory systems.

Order: Pharyngobdellida.

Specimens have no teeth and a nonprotrusible pharynx; they suck blood by means of their strong muscular pumping pharynx (armed with one or two stylets but no teeth), are provided with three or four pairs of eyes, and contain red blood in lacunae.

Important Species

See Table 1.

Integument

As in other members of the phylum ► **Annelida**, the leeches are covered by a unilayered, cellular epidermis which excretes to its surface a thin ► **cuticle** consisting of a proteinaceous ground substance including collagen fibers. ► **Chitin** is only present in the rigid bristles (chaeta) which are, however, absent in most hirudineans except *Acanthobdella*. This ► **cuticle** remains very elastic and is molted several times (not at definite intervals) in Hirudinea, but not in other annelids.

Intestine and Food Uptake

The intestine of parasitic leeches consists of a frequently armed mouth, a pharynx, an esophagus, a stomach, an intestine with 6–7 large paired diverticles, a hindgut, and the rectum ending with the anus (► *Hirudo medicinalis*/Fig. 1). In the medicinal leech *H. medicinalis*, the teeth of the

Leeches, Table 1 Some common species of leeches (Hirudinea)

Pharyngobdellidae		
<i>Erpobdella octoculata</i>	20	Predacious leeches, feed on insect larvae

three jaws are pored by the canaliculi of unicellular glands, which produce, besides anesthetic and vasodilatory compounds, an anticoagulant (hirudin) which acts as an antithrombokinase. Due to this fact, a large leech may ingest about 15 g blood (i.e., tenfold his own body weight) within a few minutes. This phenomenon was used for centuries in human medicine as a general remedy (Introduction). The blood cells are stored in the intestinal diverticles, while the fluid compounds are rather quickly excreted. This amount of blood allows the leeches to survive starving periods of up to 2 years. The blood cells inside the intestine are retained due to the activity of the hirudin in full shape for a long time and become digested bit by bit due to the activity of a particular bacterium (*Pseudomonas [Aeromonas] hirudinis*) instead of its own digestive enzymes (which,

however, are not completely absent). The bacteria are packed by the adult worm on its eggs and are thus transmitted to the next generation. Investigations of our group prove the long (half year) survival of many agents of diseases (viruses, bacteria, protozoan parasites) inside the stored blood. Furthermore, the antibodies of HIV and hepatitis B viruses were found in African leeches, so that leeches pose a considerable danger for their hosts.

Excretory System

The excretory system of leeches consists of 10–17 pairs of ► [metanephridia](#) (► [Hirudo medicinalis](#)/Fig. 1) which each opens with a porus at the ventral body surface. They start with a ciliated funnel that opens into the body cavity or into a spherical nephridial capsule (depending on the species) and collect materials to become excreted.

Nervous System

The nervous system of leeches (► [Hirudo medicinalis](#)/Fig. 1) corresponds in principle to that of other annelids while being composed of a ventral chord system with a typical broad fused ganglion in each segment. From there 3–4 ringlike running pairs of nerves extend to the periphery. The ganglia of the segments of the posterior sucker are fused to form a large terminal ganglion. Anteriorly, a supraesophageal ganglion is developed innervating sensillae of various types. This epi- = supraesophageal ganglion is connected to the subesophageal ganglion which innervates the mouth and the anterior intestine.

Leeuwenhoek, Antony van (1632–1723)

Developer and user of the first type of microscope, described, e.g., human sperms, Giardia, etc.

Leidy, Joseph (1823–1891)

German-American anatomist, discoverer of the muscle stages of *Trichinella* (1846) and recommending to eat only cooked meat. In 1886 Leidy described the hookworm of cats.

► [Leishmania](#).

Leishman, William Boog (1865–1926)

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Scottish pathologist and medical officer of the British Army in overseas (mainly in India), finally ranked as general manager of the Army Medical Services during the last 3 years of his life (Fig. 1). While he stayed in India, he studied patients suffering from enteric fever and kala-azar (= the Indian name for the disease, which ► [Ross](#) later called “leishmaniasis,” honoring Leishman’s merits in the discovering of this parasitosis. In

1903, he published tiny ovoid stages seen in tissues of kala-azar patients. They were later called Leishman-Donovan bodies (since ► [Donovan](#) detected similar ones). Today, it is known that these bodies are the amastigote (= micromastigote) stages of the *Leishmania* species. Ronald Ross (= the winner of the second Nobel Prize in Physiology or Medicine) as well as Leishman and Donovan were honored by the English Court by the award of the title “Sir.” Leishman’s amendment of the so-called Romanowsky stain by adding methylene blue and eosin to color the *Leishmania* stages is still used today.

Leishmania

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Classification

Leishmania is a genus of ▶ Trypanosomatidae, named after Sir William Leishman (1865–1926).

Important Species

See Table 1 and Figs. 1, 2, 3, and 4.

Life Cycle

See Fig. 1.

Surface Coat

Besides several GPI-anchored glycoproteins on the surface of Leishmania spp., the major component of the ▶ surface coat in these parasites is represented by a ▶ lipophosphoglycan which is also a ▶ GPI-anchored family of molecules harboring a large glycanic moiety mostly made of repeats of a disaccharide phosphate motif that differs in size and terminal ▶ capping sugars among developmental stages. LPG stage-specific differences are responsible for the specific interaction of the developmental stages with their respective target cells or organs.

Leishmania, Table 1 Important Leishmania spp. parasitizing humans

<i>L. donovani infantum</i>	Visceral, infantile	Dogs	Mediterranean countries	<i>Phlebotomus</i> spp.
<i>L. donovani chagasi^b</i>	Visceral	Foxes, cats, dogs	South America	<i>Lutzomyia</i> spp.

^aSome cutaneous species may also initiate visceral leishmaniasis
^bSome authors keep this species synonymous to *L. infantum*

Leishmania, Fig. 1 Life cycle of *Leishmania* spp. (see Table 1). 1 After the bite of the vector, the injected promastigote stage is engulfed by macrophages in the skin of the vertebrate host. 2 Transformation of promastigotes into amastigote stages (2–4 µm in diameter) requires 1–4 h; reproduction proceeds as binary

fission inside a parasitophorous vacuole, which later breaks down. 3 When macrophages are closely filled with amastigotes (after 48 h), they finally burst and set free the parasites which may enter other macrophages in the skin, leading to a cutaneous leishmaniasis (Leishmaniasis, Man/Fig. 2). 3.1 Amastigotes of the

Host Cell Invasion

In this group, two forms of the parasite are invasive: the promastigote (due to extracellular multiplication in the vector) and the amastigote (due to intracellular development). The target of these parasites is essentially a phagocyte (monocyte, macrophage). They have been described as entering the host cell via phagocytosis (► [Host Cell](#)

Leishmania, Fig. 2 LM of a Giemsa-stained blood smear. Several amastigotes of *Leishmania* spp. are situated closely to two red host cell nuclei, the cells of which were disrupted. Note inside the amastigote, the small red-colored kinetoplast and the larger nucleus

[Invasion](#)/Fig. 1) although some participation of the parasite cannot be completely excluded. The *Leishmania*-containing phagosome then acquires properties of late endosomes-lysosomes and is therefore a particular compartment of the host cell, partly connected to the vesicular traffic of the cell. This compartment has a low pH (around 5), and its membrane contains the major lysosomal glycoproteins (LGPs) and the proton ATPase. The vacuole is readily accessible to the fluid-phase ► [endocytosis](#) pathway of the host cell, but accessibility to receptor endocytosis markers is not universal, showing that this vacuole is not simply a lysosome. Promastigote-to-amastigote transformation occurs in this compartment before parasite multiplication. An intriguing feature of *Leishmania* invasion is that the ► [vacuoles](#) formed by the different species do not possess the same properties with regard to their size and their interaction with the endosomal compartment of the host cell, and this may have consequences for the respective pathogenicity of these parasites.

Adaptation of *Leishmania* amastigotes to optimal survival at low pH under the adverse conditions of a lysosome is not fully explained; high levels of glycoinositol phospholipids and glycosphingolipids may be in part responsible for this unusual resistance.

Transformation Inside the Vector

If a female *Phlebotomus* has taken up amastigotes of *Leishmania*, they are transformed within 24–48 h in the foregut into procyclic stages,

Leishmania, Fig. 1 (continued) *L. donovani* group are carried to inner organs and may enter various host cells, where they are reproduced by repeated binary fissions and lead to a visceral leishmaniasis within 4–6 months (*kala-azar*, *dumdum* fever; ► [Leishmaniasis](#), [Man](#)/Fig. 1). 4–7 When a sand fly (genera ► [Phlebotomus](#), ► [Lutzomyia](#)) ingests amastigotes along with its blood meal, the latter are transformed into slender ► [promastigotes](#) (10–20 µm in length) in the midgut, where they multiply by repeated

► [binary fission](#) (6). Quickly they block up the gut of the vector and move to the pharynx and buccal cavity, where they are injected into a new host with the fly's next bite (7). All stages have a slight ► [surface coat](#). *AM* ► [amastigote stage](#), *B* basal body of flagellum, *DI* dividing stage, *F* free flagellum, *FV* food vacuole, *IN* intestinal cell, *K* ► [kinetoplast](#), *MA* macrophages, *N* nucleus, *NH* nucleus of host cell

Leishmania, Fig. 3 SEM of a dividing promastigote (= infectious stage)

Leishmania, Fig. 4 SEM of an amastigote stage of *Leishmania* in a host cell

which transfer inside the terminal midgut (enclosed within the ► [peritrophic membrane](#)) to nectomonads (= swimming promastigotes) within 48–72 h. Later (within 4–7 days) leptomonads (= slender promastigotes) and haptomonads (wall-attached forms) occur prior to the occurrence of the transmissible metacyclics, which are found around days 6–7 at the inner side of the stomodeal valve. During the next sucking activity of the *Phlebotomus*, these stages are regurgitated into the wound.

► [Leishmaniasis, Animals](#) and ► [Leishmaniasis, Man](#).

Leishmania Donovanii Complex: Survey

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

The genus name honors W.B. ► [Leishman](#) (1863–1926); the genus name is dedicated to his English colleague Charles Donovan (1863–1951). Both contributed most essential knowledge on these parasites.

Geographic Distribution/Epidemiology

The parasites and the induced disease are found in dry, sandy, and mountainous regions. *Leishmania donovani donovani*: India, China, Central Asia, East Africa from Egypt to Kenya and Uganda, West Africa: Senegal, Mali, Nigeria; *L. donovani infantum*: Balearic Islands, Corsica, Sardinia, Coasts of the Mediterranean Sea, regions of the Black Sea; oriental countries: Saudi-Arabia, Yemen, Iraq, Iran, Emirates, Ethiopia. *L. donovani chagasi*: Middle and Central South America: local spots from Mexico until South Brazil. In total more than 100 millions humans are infected.

Morphology/Life Cycle

It is still finally not solved, whether the *L. donovani* complex consists of three true subspecies or whether there are three different species. However, there is no possibility to decide by means of morphological criteria nor by significant molecular biological facts. The infections start by bites of infected sandfly (e.g., ► *Phlebotomus* species in the case of *L. d. donovani*, *L. d. infantum* respectively ► *Lutzomyia* species in *L. d. chagasi*). During these bites promastigotes (sized 8–10 µm in length; Figs. 1 and 2) are transmitted. Within the skin region they were ingested by macrophages and included within food vacuoles (Figs. 3 and 4). Therein they are transformed during binary fissions to ovoid amastigotes = micromastigotes with a length of about 2–4 µm. Their tiny, short flagellum, which originates in a short invagination, never surmounts the cell surface, so that it becomes only visible in electron micrographs (Fig. 4). The parasitized host cell finally ruptures and sets free these micromastigotes, which either enter other cells in the skin region (so that also lesions may occur there) or are transported by lymph or blood to inner organs, where the characteristic further development occurs. Thus shortly after the skin reproduction phase the parasites are found in the reticuloendothelial system of the intestine, liver, spleen, lymph nodes, and bone marrow. In case a

female sandfly ingests in such micromastigote stages they are transformed in the anterior portion of the intestine into promastigotes, which divide themselves repeatedly by longitudinal binary fission. During each of the following sucking acts the sandflies inject some of these promastigotes into the new host, so that a new cycle may start. Besides humans many reservoir hosts are known. Several live close to humans and thus are the main source for human infections. In the case of *L. d. infantum* dogs, wolves, foxes, raccoons, and rats are most important, while *L. d. chagasi* apparently only appears in foxes and dogs in larger amounts. Infections with *L. donovani* apparently induce a strong immunity after the infection had been cured by treatment using medicaments.

Symptoms of Disease

Depending on the region of occurrence the disease due to *Leishmania donovani* has got different names: Kala Azar, e.g., in India, Dum-dum fever, black disease, visceral or intestinal leishmaniasis. In most cases – although the parasites divide themselves constantly and become increased in number – significant symptoms do not occur for a long period after the infection. Thus there appear often first symptoms only after weeks or even after several months. Then start long lasting fever (for weeks with only short interruptions), which reach 39–40 °C (without chills). After weeks fever declines to a subfebrile status. During the phase of high fever mostly two peaks occur within 24 h. Another **leading symptom** of the visceral leishmaniasis is besides the long lasting fever the increasing splenomegaly (increase of spleen), occasionally accompanied by lymph node swellings and hepatomegaly (liver swelling). In the following period of disease anemia occurs as well as leucopenia with decreasing numbers of 2,000 leucocytes per mm³ (found in up to 75 % of the cases). The number of thrombocytes decreases also significantly, while eosinophilia does not belong to the criteria of this type of leishmaniasis! When looking at the results of electrophoresis the amount of gammaglobulines is strongly increased, while albumin has

Leishmania Donovanii Complex: Survey, Fig. 1 Life cycle of *Leishmania* spp. 1 After the bite of the ►vector the injected promastigote stage is engulfed by macrophages in the skin of the vertebrate host. 2 Transformation of ►promastigotes into amastigote stages (2–4 µm in diameter) requires 1–4 h; reproduction proceeds as ►binary fission inside a ►parasitophorous vacuole, which later breaks down. 3 When macrophages are closely filled with ►amastigotes (after 48 h), they finally burst and set free the parasites which may enter other macrophages on the skin, leading to a cutaneous leishmaniasis. 3.1 Amastigotes of the *L. donovani* group are carried to inner organs and may enter various host cells, where they are reproduced by repeated binary fissions and lead to a

visceral leishmaniasis within 4–6 months (kala-azar, dum-dum fever). 4–7 When a sandfly (genera ►*Phlebotomus*, ►*Lutzomyia*) ingests amastigotes along with its blood meal, the latter are transformed into slender ►promastigotes (10–20 µm in length) in the midgut, where they multiply by repeated ►binary fission (6). Quickly they block up the gut of the vector and move to the pharynx and buccal cavity, where they are injected into a new host with the fly's next bite (7). All stages have a slight ►surface coat. AM amastigote stage, B basal body of flagellum, DI dividing stage, F free flagellum, FV food vacuole, IN intestinal cell, K ►kinetoplast, MA macrophages, N nucleus, NH nucleus of host cell

Leishmania Donovanii Complex: Survey, Fig. 2 Scanning electron micrograph of a dividing promastigote stage in the intestinal tract of a sandfly

Leishmania Donovanii Complex: Survey, Fig. 3 Light micrograph of a macrophage with disrupted cell membrane containing large numbers of amastigotes. *E* erythrocyte, *K* kinetoplast, *N* nucleus of the parasite, *NH* nucleus of the host cell

Leishmania Donovanii Complex: Survey, Fig. 4 Transmission electron micrograph through an amastigote = micromastigote stage inside of a macrophage. Note that the flagellum (above nucleus) does not leave the flagellar pocket

decreased. The change in protein composition and the anemia may initiate a sudden erythrocyte sedimentation. The color of the skin – especially of the face of patients – may reach extremely pale aspects. Untreated cases of this type of leishmaniasis end within a period of ½ and 3 years in cachexia and death mostly accompanied by bacterial superinfections. For **differential diagnosis** other diseases which induce also symptoms like splenomegaly (and/or leucopenia and anemia) must be considered in the first phase of *L. donovani* infection: e.g., malaria, typhus, miliar tuberculosis, sepsis, brucellosis, schistosomiasis. In the second phase of *L. donovani* infections other diseases such as lymphomas or leukemia may start additionally.

In treated cases of a *L. donovani* infection late symptoms may occur beginning 1-10 years after treatment, which are called “**dermal post Kala-Azar leishmanoid**” (DPKL), which is characterized by the formation of strongly pigmented or erythematous skin lumps. This late symptom occurs in 20 % of cases in India and in 2 % of the cases in Africa. These lumps are mainly found in the face.

Diagnosis

In *Leishmania donovani* infected persons tissue probes taken from spleen, bone mark, lymph nodes, or liver contain the micromastigote stages, which can be seen microscopically in Giemsa stained smear preparations. However, in case of probes of the spleen there is a high risk, since leishmaniasis is linked with thrombopenia and thus there exists a decreased blood cell coagulation. Probes can also become inoculated in tissue cultures and in golden hamster. Positive reactions in hamsters, however, only occur after 6–8 weeks. PCR tests and/or serological examination (IFT, ELISA, and other methods) show mostly high levels of antibodies. General symptoms are hypergammaglobulinemia, anemia, and pancytopenia. **Attention:** false positive results may also occur when using serological methods, since cross reactions with cutaneous and/or mucocutaneous leishmaniasis respectively Chagas disease

are possible in the final stage of the disease or in case of immunosuppressed persons.

Infection

Percutaneous injection of promastigote stages during bites of sandflies in endemic regions.

Prophylaxis

Use repellents (Viticks[®], Autan[®]); spray them onto skin and clothes in endemic regions. **Attention:** repellency lasts only a few hours!

Incubation Period

Ten to sixty days, in rare cases also 1 year or more.

Prepatency

One to three weeks.

Patency

Months until years. However, self-healing is extremely rare. Thus without treatment this type of leishmaniasis ends mostly fatal for the patient.

Treatment

Glucantime (20 mg/kg bodyweight) i.v. twice at intervals of 28 days. Alternatives in cases of antimony resistance or intolerance are pentamidine and amphotericin B. Paromomycin (i.m.) and allopurinol and combinations of antimony preparations together with gamma-interferon had also been used successfully. Miltefosin (Impavido[®]) is used orally: 3 doses per day of a total of 1.5–2.5 mg per kg bodyweight are given for 25–30 days.

Leishmania Species of Skin: Survey

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

The genus name honors the English scientist W.B. Leishman (1865–1926). The species names show regional relations, honor the English scientist Charles Donovan (1863–1951) or refer to main hosts: Latin: *infans* = child.

Geographic Distribution/Epidemiology

The different species of the genus *Leishmania* have entered different regions:

Leishmania donovani infantum (found in dry, sandy mountain regions of countries around the Mediterranean Sea)

L. tropica (found in countries of the Southern Balcony, Greece, Turkey, Caucasian region, Arabian coasts, Afghanistan, Pakistan)

L. major (Northern Africa, anterior oriental regions, Lebanon, Syria, Iraq, Iran, Northern Saudi Arabia. Southern Afghanistan, Pakistan, Black Sea region, Western Africa between 10th and 13th°, local regions in Central and Western Africa)

L. aethiopica (Ethiopia, Kenya, Tanzania, Namibia)

L. mexicana-complex (Texas, Mexico until northern Argentina respectively Peru)

L. braziliensis (like *L. mexicana*)

In these countries at least 100 million humans are infected, although high cure rates have been reached by medications. However, new and repeated infections lead to constant high numbers of infected people (plus reservoir hosts), so that travelers have a constant infection risk and should therefore protect themselves by use of significantly acting repellents (e.g., Viticks®) Autan based on icaridin. Table 1 shows further species of the genus *Leishmania*.

Morphology/Life Cycle

The infections of humans and reservoir hosts start by bites of the females of the sandfly genera ► *Phlebotomus* (worldwide), ► *Lutzomyia* or ► *Sergentomyia* (in South America). During bites saliva is injected that contains so-called promastigote stages (Figs. 1 and 2), which are characterized by an anterior single flagellum. They have been reproduced by longitudinal binary fission while being attached at the wall of the proventriculus of the vector sandflies. Inside the skin these stages become situated within vacuoles of macrophages, histocytes, and endothelial cells. There the promastigotes become transformed to so-called amastigote (syn. micromastigote) stages, which have a size of only 2–4 µm, possess a tiny flagellum, a typical

kinetoplast, divide themselves by binary fission, and finally destroy the host cell so that they are able to enter neighboring cells (Fig. 3). Therefore larger regions of destruction occur leading in the case of *L. tropica* to badly healing wounds in the skin. In the case of *L. donovani* stages the parasites are transported by macrophages to inner

organs (e.g., spleen, lymph nodes, center of bones, etc.), where life-threatening damages may occur. In the case that sandflies suck blood they ingest those tiny amastigotes, which are transformed to promastigotes in their anterior intestinal regions. These stages are then transmitted to other hosts during further blood meals. All

Leishmania Species of Skin: Survey,
Fig. 2 Dividing stage of a promastigote

Leishmania Species of Skin: Survey, Fig. 3 Diagrammatic representation of the process how macrophages engulf promastigotes (a–d)

Leishmania Species of Skin: Survey, Fig. 4 Transmission electron micrographs of promastigotes attracted by a protrusion of a macrophage

Leishmania species use besides humans a wide spectrum of reservoir hosts, so that eradication is practically excluded. Common reservoir hosts are *L. tropica*: dogs, rodents; *L. aethiopica*: cape hyrax; *L. mexicana* complex: rodents. Since the leishmaniasis are distributed among reservoir animals as well as among humans and since they are transmitted by sandflies the leishmaniasis is considered as a true zoonosis.

Symptoms of Disease

The skin leishmaniasis is a common term to describe a wide spectrum of clinically different diseases, which are caused by a related group of agents.

(a) Old World skin leishmaniasis

- Dry skin leishmaniasis: (*L. tropica*, *L. d. infantum*)

- Wet skin leishmaniasis, Oriental sore, Aleppo sore: *L. major*
- Diffuse skin mucosa leishmaniasis: *L. aethiopica*

(b) New World skin leishmaniasis

- Chiclero disease along the ear: *L. mexicana mexicana*.
- Espundia, leishmaniasis of mucous layers (*L. braziliensis braziliensis*),
- Uta (dry skin leishmaniasis): *L. braziliensis peruviana*,
- Diffuse skin leishmaniasis: *L. mexicana amazonensis*, *L. mexicana pifanoi*

In general the following symptoms occur: after an incubation period of about 2–4 weeks (rarely also after several months) the biting sites develop itching reddish papulae and skin nodules, which slowly enlarge into ulcerations. Their final appearance depends not only on the injected species but also on the immune system of the host. In the case of the Oriental sore of the Old World (i.e.,

Leishmania Species of Skin: Survey, Fig. 5 Light micrograph of a destroyed host cell containing numerous reproduced amastigotes

infections with *L. tropica*) self-healing may occur within 1 year (i.e., 1 year sore) if there are not superinfections with different bacteria. As remnants of the Oriental sore a flat scar occurs. In the cases of the South American skin leishmaniasis different prognoses exist depending on the species (Fig. 4):

- *L. mexicana* leads to sores comparable to *L. tropica*.
- *L. braziliensis* leads to infections of mucous layers (Espundia) introducing to destruction of the lips, mouth, or the nasal cartilage, thus producing aspects described as tapir nose and other malformations of the skin (Figs. 4 and 5).

Diagnosis

The agents of diseases (i.e., amastigote respectively micromastigote stages) can be obtained,

when smear preparations or punctate probes are fixed and colored according to Giemsa. Serological tests are common, e.g., IFT, ELISA, etc., which act well in mucocutaneous leishmaniasis but deliver poor results in cutaneous leishmaniasis. For clear species differentiation PCR techniques are most successful and can be recommended as golden standard for high-quality laboratories.

Infection

Leishmania promastigotes are transmitted during bites of sandflies of the genera *Phlebotomus*, *Lutzomyia*, or *Sergentomyia*.

Prophylaxis

Repellents based on ► [icaridin](#) (► [saltidin](#)) (e.g., Viticks®, Autan®) or DEET offer protection for up to 6 h from attacks of sandflies, while pure plant products protect for less than a half hour. Sleeping below mosquito nets in endemic regions is recommended.

Incubation Period

Two to four weeks.

Patency

Months up to years.

Therapy

In cases of uncomplicated cutaneous leishmaniasis treatment is not recommended, since drug toxicity is high and wounds will heal after a while. Only symptomatic cure is recommended by use of

Leishmania Species of Skin: Survey, Fig. 6 (a–f) Skin leishmaniasis in humans. (a) Mucocutaneous Espundia of nose and throat. (b) Espundia of lip region. (c) Chiclero's sore at the ear (*L. mexicana*). (d) Oriental sore

Leishmania: Taxonomy

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Many scientists working with different Leishmania species feel that it is needed to reconstruct the interrelationships of Leishmania species and already propose changings (e.g., Schönian et al. (2010)). Others warn that it might be too early for a fundamental revision, if not all full

genome sequences of well-chosen reference strains are available – and this will need time. Thus the present status (2014) of naming ► *Leishmania* species is shown in the present edition of the Encyclopedia of Parasitology.

Leishmaniacidal Drugs

General Information

► *Leishmania* spp. are intracellular parasites (amastigote stages) that affect mainly humans, dogs, and rodents (Table 1). The parasites are transmitted to various hosts by bites of sand flies (► *Phlebotomus* spp. and ► *Lutzomyia* spp., small in size). *Leishmania* invades resting macrophages and reaches cells of the reticuloendothelial system in various organs causing inflammatory processes and immune-mediated lesions. *Leishmania* can cause various disease patterns. Leishmaniasis comprises a variety of syndromes ranging from asymptomatic and self-healing infections (e.g., single cutaneous lesions caused by *L. major* or *L. tropica*) to those with a significant ► morbidity and mortality. The lesions may be confined to skin or disseminated to various tissues as in the case of the potentially fatal ► visceral leishmaniasis (VL). This zoonotic form (Kala-azar, Dum Dum Fever, or ► Black Sickness) is produced by *L. donovani* in China, India, the Middle East, and Africa, by *L. infantum* in North Africa and

the Mediterranean region, and by *L. chagasi* in Latin America. Various clinical signs referring to the Old World ► cutaneous leishmaniasis (CL) are due to *L. major*, *L. tropica*, *L. aethiopica*, and certain zymodemes of the *L. infantum* complex. *L. mexicana* complex and *L. braziliensis* complex cause the New World cutaneous leishmaniasis and mucocutaneous leishmaniasis (MCL) (“Espundia”); they focally occur from Texas (USA) and Mexico, southwards throughout Central America and South America as far south as São Paulo state of Brazil. All species except *L. tropica* are essentially ► zoonoses that occur in scattered foci primarily rural and suburban, but there is a trend towards urbanization. Annually, about 500,000 clinical cases of VL occur worldwide and more than 200 million people are exposed to infection.

Zoonotic VL in dogs is a progressive systemic disease characterized by chronic wasting. Initial clinical signs are vague and may be ► weight loss, fever, ► anorexia, and exercise intolerance. Clinical signs indicative of systemic involvement include nonpruritic skin lesions, peripheral lymphadenopathy, lameness, and epistaxis. However, there may be different clinical features depending on individual variations, species of *Leishmania*, and phase of the disease. CL is a localized skin disease, which can show cutaneous, or mucocutaneous ► nodules and ulcerations but does involve other organs. Canine leishmaniasis in the Old World is mainly due to *L. infantum* endemic in parts of Spain and throughout the Mediterranean basin where its incidence may be up to 40 %. In the New World, *L. chagasi* (reservoir crab eating “fox”, *Cerdocyon*, possibly others, dogs, serve as domestic reservoir) is the causal agent for American VL in dogs.

Drugs Acting on Leishmaniasis of Humans and Animals

Old World and the New World Leishmaniasis:

are transmitted by sand flies and caused by various *Leishmania* occurring in the Old World and the New World; in humans and animals, *Leishmania* produce numerous clinical manifestations attributed to them; thus leishmaniasis comprises a variety of syndromes ranging from asymptomatic and self-healing infections (e.g., single cutaneous lesions caused by *L. major* or *L. tropica*) to those with a significant morbidity and mortality. The lesions may be confined to skin or disseminated to various tissues as in the case of the potentially fatal visceral leishmaniasis (VL); post-kala-azar dermal leishmaniasis (PKDL) is a relatively common consequence of therapeutic cure from VL caused by *L. (L.) donovani*; amastigote (intracellular) stages can be diagnosed clinical, parasitologic, serologic, and by isoenzyme electrophoresis, and DNA-based detection; however, it may be difficult to detect amastigotes in impression smears or in biopsy material (e.g., from bone marrow); these very small spherical to ovoid stages characterized by large nucleus and a prominent ovoid or rod-shaped kinetoplast may be differentiated from organisms such as *Histoplasma* or *Toxoplasma*; *Leishmania* has recently been divided into two subgenera, *Leishmania* (*Leishmania*) (most species) and *Leishmania* (*Viannia*), e.g., *L. (V.) braziliensis* and related species, taking into consideration many factors, including morphology, biochemical, and genetic characteristics of the organisms as well as their geographic distribution, clinical manifestations, and epidemiological factors; drugs used in humans may be also used in dogs

DRUGS MAY BE USED FOR TREATMENT OF ALL LEISHMANIASIS IN HUMANS AND ANIMALS**SPECIES OCCURRING IN THE OLD WORLD**

Cutaneous leishmaniasis (=CL) (oriental sore) <i>L. (L.) tropica</i> , <i>L. (L.) major</i> , <i>L. (L.) aethiopica</i>	amastigote (parasites invade resting macrophages of the skin; infection is often confined to the dermis and subcutaneous tissue)	CL: DRUGS OF CHOICE PENTAVALENT ANTIMONIALS sodium stibogluconate (*Pentostam GSK) or meglumine antimonate (*Glucantime, Sanofi-Aventis): (20 mg Sb/kg/d i.v. or i.m. x20d, may be repeated or continued) ALTERNATIVES DIAMIDINES pentamidine isethionate (*various): (<i>L. panamensis</i> , Columbia: 2–3 mg/kg i.v. or i.m. daily or every second day x4–7 doses) AMINOGLYCOSIDE ANTIBIOTIC paromomycin (*various): (topically 2x/d x10–20d may be repeated or continued) or *Leshcutan, a special formulation with methylbenzethonium HCl in soft white paraffin	Sb compounds are generally toxic: frequent fatigue, nausea, muscle and joint pain, increased transaminases, changes in ECG (T wave inversion), occasionally hepatic and renal dysfunction; shock sudden death (rare); pentamidine may cause frequent hypotension, hypoglycaemia often followed by diabetes mellitus, renal damage, pain at injection site, GI disturbance, vomiting; it proved effective in CL patients (Columbia) where likely organism was <i>L. panamensis</i> (its effect against other species is not well established) paromomycin should be used only in regions where CL species have low potential for mucosal spread; *Leshcutan proved effective against <i>L. major</i> in Israel and Guatemala (<i>L. mexicana</i> ,

Data Given in this Table have no claim to full information

antimony gluconate and meglumine antimoniate) have been the first-line drugs for the treatment of leishmaniasis in humans. The precise chemical structure of these drugs is difficult to identify.

Thus quality control relies on chemical analysis for **pentavalent antimony** (Sb^{5+}) rather than sugar component, and other physicochemical analyses. Drug tolerance to antimonials in human and

canine leishmaniasis is known and there may be considerable rates of treatment failure and relapsing patients; drug tolerance may also be due in part to long-term treatment. Besides unresponsiveness, these drugs may show marked toxic effects such as arthralgia, nephrotoxicity, and cardiotoxicity leading in rare cases to sudden death. Antimonials are administered either by intralesional infiltration in simple single cutaneous lesions or by intramuscular injection in all cases with systemic involvement. The parenteral administration may be associated with unpleasant side effects. However these drugs seem to be safe if administered in the correct doses. Antimony is excreted quickly from the body so that daily treatment is necessary throughout each course for patients with VL (regimen see Table 1). The polyene antibiotic, **Amphotericine B**, is known to be effective in the treatment of VL, MCL (South America), and systemic mycoses but because of its toxicity it has so far been used only as a second-line drug (regimen see Table 1). There are now lipid formulations of amphotericine B with lower toxicity on the market and all have been on clinical trial for leishmaniasis. Thus the unilamellar liposome formulation, AmBisome, proved highly active against VL in Europe, Africa and India. *L. donovani* resistant to pentavalent antimony compounds may respond to lipid-encapsulated amphotericin B (NexStar is partner of TDR, WHO). In the search for nontoxic antileishmanials, attention has been directed toward currently used oral antifungal drugs such as the allylamine, terbinafine, N-substituted azoles, ketoconazole, and itraconazole. This is also true for the oral purine (hypoxanthine) analogue, **allopurinol** (see Table 1, also ► [Trypanocidal Drugs, Man/Drug Acting on American Trypanosomiasis \(Chagas' Disease\) of Humans](#)) or parenteral and topical formulations of the aminoglycoside **paromomycin** (= monomycin = aminosidine, Table 1). Most of these drugs and the 8-aminoquinoline WR6026, including synergistic combinations of antimonials either with paromomycin, allopurinol, or interferon- γ , which are or were on clinical trial for VL and CL have proved variably

effective so far and well-tolerated. VL/HIV coinfections present special problems. Indirect methods of diagnosis (► [Serology](#)) frequently fail in treated and relapsing patients and direct invasive methods and skilled microscopy are then required. DNA-based identification of parasites by means of PCR method appears to provide a solution to diagnosis of persistent infections. Standard treatment of VL with conventional drugs gives poor results with HIV patients (about 40 % relapsed or showed persistent ► [chronic infections](#)) demonstrating the importance of the immune response during chemotherapy.

Current treatment of **leishmaniasis in dogs** with pentavalent antimony derivatives and/or allopurinol does not always provide complete elimination of parasites and in most cases clinical remission. If treatment period is too short clinical relapses are common. Oral long-term treatment with **allopurinol** for 4 weeks or longer (up to several months) may lead to clinical remission after intermittent administration of the drug. Dose used is usually 10–20 mg/kg b.w. twice daily or higher (up to 30 mg/kg b.w./day) and well-tolerated (sometimes vomitus). Simultaneous administration of **meglumine antimoniate** and allopurinol resulted in maintaining clinical remission in dogs. Dose regimen for Sb was 100 mg/kg b.w. s.c. for 20 days, followed by discontinuation of treatment for 15 days and repetition of the same regimen for 10 days, and that for allopurinol 30 mg/kg b.w. p.o. for 3 months, followed by 20 mg/kg b.w. for 7 days each month. Another intermittent regimen, which has successfully been used in treating canine leishmaniasis, is the intravenous (i.v.) administration of meglumine antimoniate, alone or in combination with, oral allopurinol. The intermittent regimen with meglumine antimoniate was 50 mg/kg b.w. (diluted with 0.9 % NaCl solution) for 2 days, followed by 100 mg/kg b.w. for 8 days. After discontinuation of treatment for 14 days, the same dosage regimen was repeated. The overall maintaining clinical remission was satisfactory in most patients but bone marrow continued to be PCR positive in the majority (11 of 16) of treated dogs.

Pathology

Leishmaniosis is caused by ► [protozoa](#) of the genus ► [Leishmania](#) that affect various mammalian hosts, but disease occurs most commonly in humans and dogs. The disease in dog is caused by *L. infantum*. The parasite is obligatory intracellular. It multiplies within macrophages and other cells of the mononuclear phagocytic system and causes chronic inflammatory processes. Clinically, the disease in dogs is characterized by a chronic loss of weight, nonregenerative ► [anemia](#), intermittent pyrexia, and generalized or symmetrical lymphadenopathy. Cutaneous lesions are very common and include dry exfoliative dermatitis, ► [nodules](#), ulcers, onychogryposis (clawlike curvature of the nails), and diffuse, symmetrical, or periorbital ► [alopecia](#) (Fig. 1). Ocular lesions such as keratoconjunctivitis, uveitis, and panophthalmitis may be present. Other signs

Leishmaniasis, Animals, Fig. 1 Dog showing typical skin signs of leishmaniasis

include intermittent lameness, epistaxis, arthropathies, ascites, and intercurrent ► [diarrhea](#). During postmortem examination, generalized lymphadenopathy and hepato- and splenomegaly are also observed.

Visceral Form: Kala azar

Mucocutaneous Form: Espundia

General Information

Leishmaniasis is a disease corresponding to a large spectrum of clinical symptoms, including visceral (VL), cutaneous (CL), diffuse cutaneous (► [DCL](#)), and mucocutaneous (MCL) forms. Recent estimations indicate that more than 400 million people are at risk of catching VL and ► [CL](#) and the annual number of cases of VL or CL has turned into hundreds of thousands. The

different species are responsible for various clinical manifestations and exhibit peculiarities of their natural cycle such as animal reservoirs or species of vectors as well as epidemiological features. Therefore a universal control strategy is not possible. Species such as *L. major*, *L. tropica*, *L. braziliensis*, *L. mexicana*, and *L. aethiopica* cause mostly single, self-healing cutaneous ► **ulcers** in humans while chronic diffuse cutaneous forms or progressively destructive mucocutaneous forms occur after infection with *L. mexicana* and *L. amazonensis* or *L. braziliensis*, respectively. The most severe, visceral form (kala-azar), which is fatal, if left untreated, and affects spleen, liver, and bone marrow, is caused by *L. donovani* and *L. infantum* (► **Leishmania**).

The infections usually start in the skin after the bite of a phlebotomid sand fly which inoculates ► **Promastigotes**. In all clinical forms of leishmaniasis (see below) ► **amastigotes** multiply in monocytes. Parenchymal cells appear rarely to be involved, suggesting that organisms are phagocytized. Although the organisms are capable of multiplying extracellularly, such as in the gut of the sand fly or in culture, there appears either to be little or no extracellular multiplication in the mammalian host, where such organisms are destroyed by the processes of immunity. Traditionally *L. major*, *L. tropica*, *L. aethiopica*, *L. mexicanum*, *L. peruviana*, *L. brasiliensis*, and *L. pifanoi* have been recognized, with several subspecies. The classification of the various leishmanial groups by zymodemes and serodemes and the correlation with clinical forms is in progress.

Pathology

The primarily cutaneous forms of leishmaniasis may be limited to the skin and adjacent tissues, possibly because the temperature optimum of the causative organisms is 33–35 °C, i.e., as in the skin; also the expression of cellular immunity is impaired at lower skin temperatures. A similar situation appears to account for the superficial localization of leprosy. In contrast to this, the

organisms causing ► **visceral leishmaniasis** infect the deep tissues even though they are inoculated by ► *Phlebotomus* spp. bite into the skin.

Cutaneous Leishmaniasis (CL)

► **Cutaneous leishmaniasis** occurs in both the Old and the New Worlds, produced by ► *Leishmania tropica* and *L. mexicanum*. Lesions start as papules composed of proliferating histiocytes (macrophages) which contain numerous amastigotes (► **Pathology**/Fig. 1). The lesions are usually found on the exposed areas of the face or extremities, at the presumed inoculation site. Satellite lesions develop sometimes on skin surfaces with intact epidermis. Diagnosis is easily accomplished in histological sections or impression smears; however organisms may be sparse. The lesions become infiltrated by varying numbers of lymphocytes and plasma cells and eventually become granulomatous, containing fewer amastigotes after several weeks or months. With the development of delayed hypersensitivity the lesions ulcerate. They become secondarily infected with bacteria and the base of the ulcer contains neutrophils. The amastigotes remain in the epidermally covered areas peripheral to the ulcer and can best be isolated by aspiration from there for diagnosis in culture.

With developing immunity, the ulcers heal with granulation tissue and fibrosis, often leaving a slightly depressed scar. However, chiclero ulcers, typically on the earlobes, do not heal readily in Mexico and Central America, a fact believed to result from the lower body temperature which impairs the expression of cellular immunity.

Main clinical symptoms: Skin ► **nodules**, papulae, ulceration, necrosis.

Incubation period: 2–4 weeks up to 1 year.

Prepatent period: 1–3 weeks.

Patent period: Months.

Diagnosis: Microscopic determination of amastigotes in skin biopsies, serodiagnostic methods, ► **serology**, ► *Leishmania*/Fig. 2.

Prophylaxis: Avoid the bite of the vector.

Therapy: See ► **Leishmaniacidal Drugs**.

Leishmaniasis, Man, Fig. 1 Distribution map of skin leishmaniasis (according to WHO)

Mucocutaneous Leishmaniasis (MCL)

Mucocutaneous leishmaniasis, or espundia, caused by *Leishmania brasiliensis* complex is also transmitted by sand fly bite in South America. However, skin lesions often metastasize from the site of inoculation to other areas of skin and the mucous membranes, especially of the oro- and nasopharynx. Histologically the lesions are granulomatous with relatively few amastigotes and numerous lymphocytes and plasma cells. The lesions ulcerate, become bacterially infected, and often persist for months or years, at times destroying the cartilaginous nasal septum.

Diffuse Cutaneous Leishmaniasis (DCL)

Diffuse cutaneous leishmaniasis may be produced by a distinct species of *Leishmania*, or it may be an individual reaction, as occurs in lepromatous leprosy. It occurs in the Caribbean, Brazil, and Ethiopia (Fig. 1). Huge numbers of macrophages filled with amastigotes accumulate and develop into nodular cutaneous lesions without necrosis,

ulceration, or the formation of granulomas and accompanied by only few lymphocytes and plasma cells (► [Pathology](#)/Fig. 14).

Visceral Leishmaniasis (VL)

Visceral leishmaniasis, or kala-azar, occurs in South Europe, the Middle East, India, Africa, and focally in Central and South America (Figs. 2, 3, 4, and 5). It is produced by several forms of *Leishmania* which can be arranged into several groups according to results of isoenzyme analysis, antibody tests, and nucleic acid analysis; these groups may include species other than the classical species, *L. donovani*, *L. infantum*, in the Middle East, and *L. chagasi* in Latin America. The reticuloendothelial cells of the viscera are parasitized by amastigotes and multiply greatly, resulting in hepatomegaly and splenomegaly (up to 3,000 g) which is palpable through the abdominal wall. Splenomegaly leads to hypersplenism with erythrophagocytosis, anemia, and is accompanied by hyperglobulinemia and hypoalbuminemia. The

Leishmaniasis, Man, Fig. 2 Distribution map of visceral leishmaniasis (according to WHO)

Leishmaniasis, Man, Fig. 3 Nonhealing leishmanial wound at the arm

Leishmaniasis, Man, Fig. 4 *Leishmania* sore in the face

lymph nodes and bone marrow are usually also involved. Impaired hematopoiesis, leucopenia, and thrombocytopenia are commonly found. Histological examination shows that the Kupffer cells of the liver and the histiocytic cells of the spleen

are filled with large numbers of amastigotes; the hepatic parenchymal cells often show steatosis and atrophy and the splenic follicles are also

Leishmaniasis, Man, Fig. 5 *Leishmania* sore at the border of the ear

atrophic. Immunoglobulins (IgA, IgM, and IgG) are deposited in the glomerular mesangia and around the tubules in the kidney. A long febrile course with progressive cachexia and secondary infection often precedes death. An unknown number of patients recover spontaneously and many do after timely chemotherapy with a regression of the reticuloendothelial ► [hyperplasia](#). Some of these patients develop post-kala-azar dermal leishmaniasis with amastigote-laden histiocytes accumulating in the skin and producing nodules covered by thin epidermis similar to an anergic cutaneous leishmaniasis (► [Pathology](#)/Fig. 14). Apparently, effector mechanisms of cellular immunity, which operate in the viscera, were not effective in the cooler skin.

Main clinical symptoms: Fever of 39–40 °C, with two peaks in 24 h, ► [anemia](#), leucopenia, pale skin, kachexia, bacterial superinfections.

Incubation period: 10 days to 1 year.

Prepatent period: 1–3 weeks.

Patent period: Months to years.

Diagnosis: Serologic tests and microscopic determination of smear preparations of bone marrow, ► [Serology](#).

Prophylaxis: Avoid the bite of phlebotomids in endemic regions.

Therapy: Treatment see ► [Trypanocidal Drugs, Man](#) and ► [Leishmaniacidal Drugs](#).

Immune Responses

In their mammalian host, *Leishmania* typically reside within macrophages, dendritic cells, and fibroblasts which not only serve as potentially safe habitats for the parasite but may also possess antigen-presenting and/or antimicrobial functions. Experimental infections of mice with either *L. major* or *L. donovani* have greatly attracted many immunologists over the last decades to study the role of innate or acquired immune mechanisms to control an intracellular microorganism. In particular, the existence of inbred mice which either cure or succumb to the infections has helped to define protective and nonprotective functions of the immune system.

Innate Defense Mechanisms

An initial study has demonstrated the ability of *L. major* promastigotes to activate the IL-1 promoter in macrophages via a MyD88-dependent pathway. Consistently, three studies have shown that mice lacking functional MyD88 adapter protein are very susceptible to infection with *L. major*. Contrasting with the WT mice, in the MyD88 KO mice infected with *L. major*, the Th responses were characterized by the production of high levels of IL-4 and low levels of IFN- γ . Importantly, upon treatment with exogenous IL-12 or anti-IL-4 antibodies, MyD88 KO mice develop Th1 responses and become resistant to infection. Additional studies have demonstrated that the lipophosphoglycan (LPG), a dominant molecule that covers the surface of the promastigote stage of *Leishmania*, is a TLR2 agonist. The lipid moiety was shown to be essential for TLR2 signaling by LPG, suggesting the involvement of the GPI anchor. Together, these results indicate that LPG is an agonist for TLR2 and that induction of IL-12 synthesis and protective immunity during infection with *L. major* in mice involves the TLR signaling pathway. While noninfective, procyclic *Leishmania* promastigotes are sensitive to complement-

mediated lysis, the infective stages transmitted by ► **sand flies** (metacyclic promastigotes) are relatively resistant to direct serum killing. As shown recently by Dominguez and Torano, *Leishmania* promastigotes bind natural anti-*Leishmania* IgM antibodies within 30 s, which then activate the classical complement pathway resulting in opsonization by the third component of complement. The opsonized promastigotes then bind quantitatively to erythrocyte CR1 receptors. Progression of infection implies promastigote transfer from erythrocytes to monocytes/macrophages where the parasite uptake is predominantly mediated by CR3. Since cross-linking of the CR3 does not elicit an oxidative burst in monocytes, complement components of the host are used by *Leishmania* for silent invasion of host macrophages. Macrophages harbor *Leishmania* and allow the parasite to replicate or when activated by appropriate stimuli such as IFN- γ kill and destroy the parasites. Toxic nitrogen products, predominantly ► **nitric oxide**, which are synthesized by iNOS, are the main parasitocidal molecules produced by activated macrophages. Mice genetically deficient for iNOS or treated with iNOS inhibitors are unable to restrict parasite replication and reactivation of latent leishmaniasis occurred after treatment of long-term-infected C57BL/6 mice with the specific iNOS inhibitor L-iminoethyl-lysine (L-NIL). In addition, iNOS appeared to have important immunoregulatory functions during the early phase of a *Leishmania* infection. At day 1 of infection genetic deletion or functional inactivation of iNOS abolished the IFN- γ and NK cell response, increased the expression of TGF- β , and caused systemic parasite spreading. Since neutralization of IFN- α/β in vivo inhibited iNOS expression and mimicked the phenotype of iNOS-deficient mice, type I interferons and iNOS are critical regulators of the innate immune response to *L. major*.

More than macrophages, dendritic cells are extraordinarily efficient in presenting antigens to naive T cells. Langerhans cells of the skin ingest *Leishmania* parasites, process native antigen, and express relevant epitopes in context with MHC molecules on their surface. The Langerhans cells move to the draining lymph nodes where they

activate parasite-specific naive T cells. Evidence suggesting that this takes place not only in experimentally infected mice but also in humans comes from immunohistochemical investigations of biopsy material from patients with cutaneous leishmaniasis: Langerhans cells containing *Leishmania* antigens have been found in the epidermis and dermis at the site of an oriental sore.

Homogeneous populations of mouse mast cells released preformed mediators such as b-hexosamidase or TNF in response to living *Leishmania* promastigotes. By local cutaneous reconstitution of mast-cell-deficient mice, it was found that the presence of mast cells augmented the lesion size caused by *L. major*. However, there was no influence of mast cells on the cytokine response in the draining lymph nodes or the ultimate outcome of the infection.

Studies with *L. major*-infected mice pointed at NK cells as an important source of IFN- γ during the early course of infection. Genetically resistant mice had a higher NK 7activity after infection than susceptible mice and the depletion of NK cells resulted in less IFN- γ production and a transient increase in lesion size. On the contrary, activation of NK cells in susceptible mice by injection of poly I-C enhanced IFN- γ synthesis and led to lower parasite burdens. However, the effects of NK cells appeared to be transient and did not influence the ultimate outcome of experimental *L. major* infections. C57BL/6 mice deficient in NK cell activity due to the beige mutation were less able to control *L. donovani* infection compared to normal control mice and reconstitution with NK cells restored this defect. While in lesions of patients with cutaneous leishmaniasis high numbers of NK cells have been detected, impaired NK activity has been found in the blood of patients with visceral leishmaniasis, which could be restored in vitro by incubation with IL-2.

B Cells and Antibodies

In vivo, B cells respond to *Leishmania* infections by production of parasite-specific antibodies, which are generally considered not protective against the intracellular *Leishmania*. The levels of *Leishmania*-specific antibodies may be very

high and in most severe infections an unspecific polyclonal B cell activation leading to hypergammaglobulinemia occurs additionally.

Although B cells cannot be infected by Leishmania parasites, activated B cells are able to process and present leishmanial antigens to T cells. It has been proposed that antigen presentation by B cells is involved in the generation of a Th-2 response. In fact, BALB/c mice treated neonatally with anti-IgM were resistant to *L. major*, and BALB/c X-linked immunodeficient (Xid) mice, which lacked the B1 subset of B cells, displayed enhanced resistance to *L. major*. In line with these findings, the cotransfer of B cells converted resistance into susceptibility in T cell-reconstituted, *L. major*-resistant scid mice. However, more recent experiments with mice harboring a targeted disruption of the IgM locus (μ MT mice) and therefore lacking B cells showed no influence of B cells on the polarization of T helper cells: μ MT mice on the BALB/c background were susceptible to *L. major* infection and developed a Th2 response.

T Cells and Cytokines

A significant increase of γ/δ T cells was found in skin lesions of patients with cutaneous leishmaniasis. Similarly, expansion of γ/δ T cells has been observed in genetically resistant mice following *L. major* infection, indicating that γ/δ T cells may be involved in host defense against this parasite. However, C57BL/6 knockout mice lacking γ/δ T cells (TCR $\delta^{-/-}$) effectively controlled the infection and produced similar levels of IFN- γ when compared with control mice, strongly arguing against an essential protective role of this T cell subset in *Leishmania* infection. In contrast, mice depleted of or genetically deficient for conventional α/β T cells were unable to control leishmania parasites. While ample evidence has demonstrated the central role of CD4⁺ Th cells in the control of a *L. major* infection, the role of CD8⁺ T cells in cutaneous leishmaniasis is less well defined. Although CD8⁺ T cells appear to be important for resistance to a secondary challenge with *L. major*, there appears to be no essential function of CD8⁺ T cells in primary infection. Both, mice genetically deficient for β 2-

microglobulin and CD8 thus lacking CD8⁺ T cells were able to mount an effective and long-lasting immune response against *L. major*.

Unlike the *L. major* model, resolution of primary *L. donovani* infection requires not only CD4⁺ T cells but also CD8⁺ T cells. Acquisition of resistance involves the secretion of IL-2, IFN- γ , and TNF. Similar to cutaneous leishmaniasis, resistance of *L. donovani*-immune mice to rechallenge was strongly dependent on CD8⁺ T cells.

Mice from the majority of inbred strains (C3H/He, B10.D2, C57BL/6, Sv129/Ev, etc.) are resistant to infection with *L. major*, while only mice of a few strains such as BALB/c develop progressive lesions and succumb to the infection. Healing of lesions induced by *L. major* requires the induction and expansion of specific CD4⁺ Th1 cells that are restricted by MHC class II and produce IFN- γ , while susceptibility was found to be associated with the development of a predominant Th2 cell immune response. However it has been shown that susceptibility is not an absolute trait but one conditional on parasite dose, since infection with low numbers of parasites (about 1000-fold lower than the number employed (10^5) to define the susceptible phenotype of BALB/c mice) induced long-term protective Th1 immunity in BALB/c mice. Thus in addition to host factors the parasite dose determines the Th1/Th2 nature of the response to *L. major*, and this was found to occur independently of the infection route and parasite strain. A large number of studies has focused on the immunoregulatory mechanisms determining the Th1/Th2 decision and the role of these different Th cells in *L. major*-infected mice.

The role of IFN- γ in the control of infection with *L. major* was firmly established by experiments showing that genetically resistant mice with disrupted genes for IFN- γ or its receptor failed to resolve their lesions. More recently, the additional importance of the Fas-Fas-L pathway in the elimination of parasites has been demonstrated. In contrast to wild-type C57BL/6 mice *gld* or *lpr* mice lacking either a functional Fas or Fas-L were unable to resolve *L. major*-induced lesions although they mounted a normal Th1 response

and their macrophages produced normal levels of NO in response to IFN- γ in vitro. Since IFN- γ upregulated the expression of Fas on *L. major*-infected macrophages, thereby rendering these cells susceptible to apoptotic death by Th1 cells, IFN- γ might contribute by at least two mechanisms to the defense against intracellular Leishmania.

Th1 and Th2 cells develop from a common native precursor. Both accessory molecules and cytokines are known to influence the differentiation of CD4⁺ T cell precursors in vivo. CD80 (B7-1) and CD86 (B7-2) as well as the CD40 molecule and its ligand have been shown to influence the Th cell differentiation and thus the clinical outcome after infection with *L. major*. Deficiency in either CD40 or its ligand resulted in the inability of mice to generate a Th1 response and to control *L. major* or *L. amazonensis* infections. While the blockade of CD86 by mAb treatment ameliorated the infection and inhibited Th2 development in BALB/c mice, BALB/c mice deficient for CD28, a ligand of CD80 and CD86, remained susceptible to infection. In contrast, the interaction of the CD4 molecule with MHC class II appeared to be of importance for the development of a Th2 cell immune response. There is ample evidence that IL-4 is essential for the development of Th2 cells after infection with *L. major*. The neutralization of IL-4 by mAb or recombinant soluble forms of the IL-4 receptor resulted in Th1 development in BALB/c mice which thereby controlled primary *L. major* infection and became resistant against secondary challenge infections. Confirmatory evidence came from experiments with mice deficient for either IL-4 or STAT-6 (one of the major IL-4 signal-transducing molecules) which were more resistant against *L. major* or *L. mexicana*, respectively, when compared with their control littermates. Only in susceptible BALB/c mice there was a very early IL-4 production by activated CD4⁺ T cells during the first day after infection with *L. major*. A highly restricted subpopulation of CD4⁺ T cells expressing the TCR V β 4 and V α 8 chains specific for a single immunodominant antigen called LACK (Leishmania-activated C kinase) was identified as source for the early IL-4. Interestingly, mice

deficient in V β 4 mounted a polarized Th1 response and were fully resistant to infection, suggesting that a single epitope of the LACK antigen drives the early IL-4 response and instructs subsequent Th2 differentiation and susceptibility to infection in BALB/c mice. In agreement with this concept, transgenic BALB/c mice expressing the LACK antigen in the thymus were tolerant to this antigen and resistant to infection with *L. major*. However, since LACK appears not to be the dominant antigen in MHC haplotypes other than H-2^d (N. Glaichenhaus, personal communication) it remains to be determined which antigen(s) or mechanism(s) are responsible for the susceptible phenotype of BALB congenic mice.

The essential role of IL-12 for the development of a protective Th1 cell response against *L. major* has been demonstrated by several experimental approaches. Neutralization with antibodies or disruption of the IL-12 gene in resistant mice resulted in susceptibility, while treatment of BALB/c mice with recombinant IL-12 during the first week of infection enabled these mice to develop a Th1 response and allowed the resolution of lesions. In line with this, mice deficient for the transcription factor IRF-1 (Interferon regulatory factor 1) were susceptible to *L. major*, most likely due to the impaired ability of their macrophages to produce IL-12. While in resistant C3H mice an enhanced expression of the IL-12 receptor subunits β 1 and β 2 was detected after *L. major* infection this was not the case in lymph nodes of BALB/c mice unless these mice were rendered resistant by neutralization of IL-4 or treatment with IL-12. Thus, the upregulation and maintenance of IL-12 receptor molecules or its counterregulation by IL-4 on CD4⁺ T cells may be critically involved in the generation of a protective Th1 cell response. The nonhealing lesions caused by *L. major* in mice were associated with enhanced IL-10 production and T_{reg} presence at the site of infection. Enhancement in the number of natural T_{reg} in mice chronically infected with *L. major* was sufficient to trigger disease reactivation and to inhibit the effector memory response. Thus, enhancement of T_{reg} regulatory function, either from the endogenous pool or

induced by the infection, can clearly become detrimental to the host by allowing excessive parasite expansion. On the other hand in the nonhealing model of *L. major* infection, pathology is also held in check by natural T_{reg} . *Leishmania amazonensis* infection in mice is characterized by the accumulation of natural T_{reg} at sites of infection that transiently downregulate immunopathology.

Several other cytokines are additionally involved in the regulation of immunity against Leishmania. It has been shown that leishmanial infection induced the production of active TGF- β , both in vitro and in vivo. Since application of recombinant TGF- β markedly exacerbated the disease while treatment with anti-TGF- β resulted in protection of BALB/c mice after infection with *L. amazonensis*, induction of TGF- β has been regarded as a parasite escape mechanism. TNF, which had no direct toxic effects on leishmania, was found to activate in combination with other cytokines such as IFN- γ the leishmanicidal activity of macrophages in vitro. In vivo, there were no differences in the expression levels of TNF, lymphotoxin (LT), or the TNF receptors I and II (p55 and p75) when susceptible BALB/c and resistant CBA mice were compared. Using knock-out mice deficient for either TNFRp55, TNFRp75, or both receptors it was reported that the TNFRp75 plays no essential role in *L. major* infection while the TNFRp55 might be required for optimal macrophage activation. TNFRp55-deficient mice developed larger lesions than control mice and failed to resolve these lesions. However, they were able to eliminate parasites within these lesions. Migration inhibitory factor (MIF), granulocyte-macrophage colony stimulating factor (GM-CSF), and IL-7 were found to enhance leishmania killing by macrophages in vitro. While MIF delivered via a Salmonella-based expression system in vivo enhanced resistance of mice, application of GM-CSF or IL-7 surprisingly caused aggravation of lesions in *L. major*-infected mice. Cytokines such as IL-10, TGF- β (see also above), and IL-13 have been found to deactivate macrophages and to enhance intracellular survival of leishmania. With the exception of TGF- β , the role of these proteins

during an immune response against leishmania in vivo remains to be determined.

The expression of chemokines has been analyzed in lesions of patients with localized cutaneous leishmaniasis and diffuse cutaneous leishmaniasis. While high levels of macrophage chemoattractant protein 1 (MCP-1) and moderate levels of macrophage inflammatory protein 1 α (MIP-1a) were detected in the localized forms of leishmaniasis, the pattern was reversed in diffuse cutaneous leishmaniasis, suggesting a functional role of these chemokines in the differential recruitment and activation of macrophages in the different forms of cutaneous leishmaniasis.

It is important to emphasize that susceptibility or resistance to *L. major* most likely involves several mechanisms since it appears to be controlled by several genes. Six loci located on the mouse [▶ chromosomes](#) 6, 7, 10, 11, 15, and 16 were found to be associated with resistance to *L. major* in BALB/c $\times$ B10.D2 backcross mice. Another study analyzing (BALB/c $\times$ C57BL/6) F2 mice showed a linkage to the h2 region on chromosome 17 and to chromosome 9.

Although *L. donovani* and *L. chagasi* also readily parasitize and cause noncuring visceral infection in inbred mice, these leishmania species do not regularly provoke an active, functional Th2 response in experimental infection as they seem to induce in human disease. The one reported exception was in mutant C57BL/6 ep/ep (pale ear) mice in which noncuring *L. donovani* infection was related to multiple host defense defects including an active Th2 response. In most other cases noncuring *L. donovani* infection has been ascribed to the failure to properly express a Th1-associated cytokine response rather than to dominant activity of Th2 cells.

In mice the susceptibility to infection with intracellular parasites such as *Salmonella*, *Mycobacteria*, and *L. donovani* is controlled by the Nrampl locus (also known as *Bcg*, *Ity*, or *Lsh*) on chromosome 1. The integral membrane protein Nrampl is expressed exclusively on professional phagocytes in the late endocytic compartments. Since a single nonconservative amino acid exchange at position 169 of this protein resulted in enhanced susceptibility of mice to *L. donovani*, the

Nramp1 protein may alter the intravacuolar environment of the parasite-containing phagosome.

Evasion Mechanisms of Leishmania

The complement resistance of metacyclic leishmania promastigotes was explained by the spontaneous shedding of the lytic membrane attack complex from the parasite surface, which might be causally linked to the elongation of the phosphoglycan chain of the surface ► [lipophosphoglycan](#) (LPG). In addition, leishmanial protein kinases have been reported to phosphorylate components of the complement system, thereby inhibiting the classical and alternative complement pathway. The 63 kDa surface metalloprotease (gp63) accelerated the conversion of C3b to a C3bi-like molecule, which acts as an opsonin and facilitates the uptake of leishmania into macrophages. *Leishmania* parasites are able to invade not only macrophages but also host cells devoid of important defense mechanisms such as iNOS. Langerhans cells of the skin as well as cells negative for all classical macrophage and dendritic cell markers, presumably reticular fibroblasts, might function as safe habitats for the parasite enabling its long-term persistence. *Leishmania* parasites are able to survive in the phagosome and phagolysosome. LPG is able to inhibit phagosome-endosome fusion and scavenge hydroxyl radicals and superoxide anions which are rapidly produced during phagocytosis. In addition, the protease activity of gp63 has been shown to protect the parasites from intraphagolysosomal degradation and is required for virulence of leishmania. *Leishmania* parasites are able to interfere with both main antimicrobial effector mechanisms, the release of superoxide, and the synthesis of NO. LPG, gp63, and GPIs, a group of glycolipids related to LPG, have been shown to mediate these suppressive effects, at least in part by inhibiting the translocation and activation of the protein kinase C (PKC) of the host cell.

A further, important mechanism by which leishmania influence the host immune response is the modulation of cytokine production. As discussed above, different leishmania species induce the production of TGF- β which has been found to inhibit antileishmanial defense

mechanisms of macrophages and to aggravate the disease in vivo. The selective suppression of IL-12 p40 synthesis by macrophages mediated by phosphoglycans of the parasite occurring on the transcriptional level appears to be an important mechanism by which leishmania avoid or delay the development of a host-protective Th1 response. Interestingly, this effect appears to be cell type specific, since uptake of *L. major* amastigotes by skin-derived dendritic cells results in activation of these cells and IL-12 release.

The processing and presentation of antigen is also targeted by the parasite. It has been demonstrated that *L. donovani* amastigotes interfered with upregulation of MHC class II molecules on the transcriptional level. Downmodulation of MHC class II occurs additionally on the posttranslational level, most likely by an enhanced internalization and degradation of these molecules. In contrast to other intracellular microorganisms, *L. donovani* prevents the upregulation of costimulatory molecules like CD80 on macrophages. The recently reported finding that gp63 selectively cleaves CD4 molecules from T cells is intriguing, as CD4 via binding to MHC class II stabilizes the interaction between antigen-presenting cells and T helper cells. A phenomenon called antigen sequestration not allowing the transport of sufficient numbers of MHC-peptide complexes to the cell surface may let infected macrophages go unnoticed by T helper cells. The molecular mechanism of this phenomenon is not yet defined, and prevention of intracellular protein degradation appears only partially responsible.

In addition to the numerous ► [evasion mechanisms](#) of *Leishmania* species summarized above, the saliva of the parasite-transmitting sand fly exerts various immunomodulatory functions. Saliva components, such as the peptide maxadilan, inhibited killing of *Leishmania* by suppressing the production of NO. Furthermore, sand fly salivary gland lysates were found to downregulate a Th1 but to upregulate a Th2 response in mice infected with *L. major*. Interestingly, the salivary gland lysates directly upregulated expression of IL-4 mRNA also in the absence of infection with *L. major*.

Vaccination

Although a treatment for leishmaniasis exists, it is costly and difficult to apply because it requires daily injections for weeks. Moreover, resistance against the classical antimonial treatment has been increasing and increased doses, prolonged hospitalization, and needs for second treatment can be necessary. Thus, an effective and affordable vaccine remains the only realistic hope of controlling such a parasitic disease. This has been the goal for many years of the tropical disease research program of the WHO, which plays a major role in *Leishmania* vaccine development and several formulations are currently under trial with encouraging results.

The use *L. major* mouse model of *Leishmania* infection has been helpful for the understanding of mechanisms involved in immunity to leishmania. It was first observed that genetically different mice presented a different degree of susceptibility to the *L. major* infection, with some strains such as C57BL/6 being resistant (spontaneous healing of controlled cutaneous lesion) while others such as Balb/c are susceptible and present progressive disease. It was further demonstrated that the difference in the susceptibility was linked to the expansion of CD4⁺ T cells secreting different patterns of cytokines. Th1 cytokines such as IFN- γ in conjunction with the IL-12 and TNF- α secretion by macrophages/dendritic cells are essential for the induction of the inducible nitric oxide synthase (iNOS) leading to large amounts of NO which play a major role in the killing of intracellular *Leishmania*. In contrast, expansion of CD4⁺ T cells secreting Th2 cytokines such as IL-4, IL-5, and IL-10 but no IFN- γ in conjunction of macrophage-deactivating factors such as TGF β and/or PGE2 is commonly associated to nonhealing infection.

Recent studies have shown that the activation/differentiation of one of the Th types inhibits the induction or expansion of the reciprocal subset, via reciprocal feedback inhibition by Type 1 or Type 2 cytokines. For instance, IFN- γ inhibits the induction/expansion of TH2, and, IL4 and IL10 inhibit the induction of TH1 cells. The mechanisms leading to the expansion of Th1 or Th2 depend on early events, IL-12 secretion in the first case and IL-4 secretion in the last case. IL-12 injection has been

shown to induce protection against cutaneous leishmaniasis in susceptible Balb/c mice leading to expansion of a Th1 cell response. From these experiments, the use of IL-12 has been proposed as an adjuvant eliciting a Type 1 response for the delivery of a *Leishmania* vaccine in particular, but also in general for vaccine against other pathogens.

If these new concepts emerging from the mouse model have allowed important progress in the comprehension of the induction of anti-*Leishmania major* immune response in humans, there is still much to do in understanding the reasons why *L. major* induces generally cutaneous lesions whereas *L. donovani* leads to visceral leishmaniasis and *L. braziliensis* to mucocutaneous disease. Therefore vaccine development against leishmaniasis has proceeded, so far, entirely within empirical approach. The observation that *L. major* induces usually benign infections with spontaneous healing after 6–9 months protecting from pathogenic reinfections was the starting point of vaccine strategies known as ► [leishmanization](#). It consists in injecting viable parasites to produce a controlled lesion in a nonvisible area of the skin. This induces a significant protection against reinfection. This immunity is essentially T-cell mediated. Leishmanization was used for a long time and was until recently used in the former USSR, in Israel, and in Iran. However, the use of live organisms can induce persistence of parasites in the immune host able to cause serious diffuse or mucocutaneous lesions in cases of change of the immune status. This program has now been abandoned. With the development of *Leishmania* transfection techniques, the production of an avirulent strain lacking the dihydrofolate reductase/thymidilate synthetase gene infecting and persisting in the macrophage is an interesting alternative for attenuated vaccine. This vaccine does not induce side effects but, so far, very little is known about the long-term consequences of such vaccine in particular in HIV-infected individuals. Killed parasites have thus renewed interest. Several trials using whole killed parasites with BCG as adjuvant are under evaluation in South America (*L. braziliensis*, *L. guyanensis*, and *L. amazonensis*) and in Iran (*L. tropica* and *L. major*) and are encouraging even if they are inferior to live vaccine.

Recently significant progress has been obtained using subunit vaccines. Molecules such as gp63, gp46, PSA-2, and LACK have given interesting results in mouse models using adjuvant not appropriate to humans. Other delivery systems using recombinant bacteria such as *Salmonella typhimurium* or BCG or recombinant vaccinia virus are under study. Besides proteins, the lipophosphoglycan (LPG) seems to be an interesting candidate. It can protect mice from infection with *L. major*. Despite the prevailing dogma that only peptide can induce T cell responses, LPG is presented by Langerhans cells to the T cells, not in the context of classical MHC molecules but by the new CD1 pathway. Because of possible genetic restriction as well as their partial protective effect, such vaccine candidates have to be mixed in a cocktail vaccine and tested as one vaccine. Subunit vaccine also has the disadvantage of inducing a usually short-lived immune response. One possible solution is to use the vaccine candidates not as proteins or peptides but as their encoding DNA. Indeed DNA vaccine is particularly attractive because it can induce a long-lived immune response. The antigen is constantly produced at low doses inducing an immune response similar to the situation of natural infection. gp63, PSA-2, and LACK delivered as plasmid DNA have already demonstrated efficient protection in mice.

The first generation of *Leishmania* vaccine against CL has already shown a relative efficacy (killed parasites) that needs to be improved by use of appropriate adjuvant. However, because the preparation of such a vaccine is difficult to standardize, research on a second generation against the different forms of leishmaniasis using defined molecules is more than ever necessary.

Leishmanin Test

This test of leishmaniasis is also called Montenegro-skin-test and often used in epidemiological studies, but less important in clinical diagnosis.

Leishmaniosis: Treatment of Canines

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

First-line treatment is a combination of meglumine antimonate and allopurinol. Other options are offered by a combination of miltefosine and allopurinol or allopurinol alone.

Lemming Disease

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Trivial name of the disease due to infections with *Francisella tularensis*.

Lemniscus

String-like organ at the apical pole of
► [Acanthocephala](#).

Leopard Skin

Type of depigmentation of skin in patients with onchocerciasis.

Lemuricola pongoi

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Lepeophtheirus salmonis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Classification

Syn. *Protenterobius pongoi*. Pinworm of Pongo monkeys in Sumatra.

Lepeophtheirus salmonis is a species of ► [Crustacea](#), an order of ► [Copepoda](#).

***Lepeophtheirus salmonis*, Fig. 1** Life cycle of *Lepeophtheirus salmonis* (order Copepoda), the so-called louse of salmon. 1, 2 ► [Nauplius](#) stages (0.54–0.85 mm), free swimming. 3 ► [Copepodit](#) stage (invasive stage, 0.7 mm). 4–7 ► [Chalimus](#) stages I–IV (1.2–2.8 mm

long), engorging stages. 8a, 9a Preadult males – motile on the skin. 8b, 9b Preadult females – motile on the skin. 10a, 10b Adults (male 5 mm, female 10 mm). One generation needs about 6 weeks at a water temperature of 10–12 °C

Life Cycle

See Fig. 1.

Disease

Salmon disease: due to wounds in the skin, super-infections with bacteria or viruses occur, which – together with the sucking activity of the parasite – weaken the fish, delay growing, and even may lead to death.

Treatment

Its treatment is monthly medical bath with insecticides, Argulol™ (emamectine), Sera/Alpha-Biocare.

Lepidapedon

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of digenean trematodes that parasitizes mainly deep sea water fish (e.g., *L. sereti* in Gadiformes: Macrouridae).

Lepidapedon sereti

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Digenean fluke parasitizing deepwater fish (e.g., *Coelorinchus sereti*, Gadiformes in Vanuatu).

Further Reading

Leptoconops

Genus of ► [Ceratopogonidae](#), which attack warm-blooded animals, suck blood all 3–5 days and are known vectors of agents of diseases (viruses, protozoans, worms).

Leptomyxid Amoebae

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *leptos* = tiny; *myxa* = slimy.

These unicellular protozoans belong to the amoebian order Leptomyxida (class Tubulinea). Members of this group are in general free-living, soil inhabiting organisms. For humans and animals, they turned out to be harmless. However, some few species of leptomyxid amoebae (e.g., ► [Balamuthia mandrillaris](#)) are opportunistic pathogens.

Leptosphyra

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Genus of feather mites of birds belonging to the family ► [Analgidae](#).

Leptotheca

Myxozoan species parasitizing in the urinary system of freshwater fish.

Leptotrombidium akamushi

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Asian mite species; the larvae of this species suck lymph on the skin of humans and animals. During this process the agents of the “► [tsutsugamushi fever](#)” might be transmitted.

Lernaeidae

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und
 Parasitologie, Heinrich-Heine-Universität,
 Düsseldorf, Germany

Name: Greek: *lerna* = muddy water.

This term describes a family of copepod crustaceans, which measure as adults 5–40 mm in length, appear slender wormlike, and are

Lernaeidae, Fig. 1 Diagrammatic representation of an adult female stage of *Lernaea* sp.

Lernaeidae, Fig. 2 Freshwater fish, which is parasitized by two female lernaeids. Note the long egg sacs

anchored by help of their anterior portion deeply inside the bodies of fish (Figs. 1, 2, and 3), where they suck blood or lymph. Only the females (Fig. 3) appear crustacean-like due to the fact that they bear two egg sacs, which are typical for

Lernaeidae, Fig. 3 Antarctic fish with large lernaeids

Lernaeidae,
Fig. 4 Sectioned fish
showing how deep the
lernaeids enter

L

those primitive crustaceans. The species of the genus *Lernaea* develops via four free-living nauplius stages, one metanauplius, and five so-called copepodit stages (which are part time = temporary parasites) into adults. Fertilization occurs between female copepodit stage 4 and males which die afterward. The fertilized females penetrate the body wall of the fish with their anterior part. The time needed for maturation is temperature dependent and needs more than 100 days at 14 °C but only 7–13 days at

28 °C. Eggs are released from the egg sacs, when the nauplius stage is formed inside the egg.

Disease: Lernaeidae introduce large loss of blood and inflammations of the skin, gills, and even of inner organs and thus may lead to death (Fig. 4).

Treatment: Masoten[®] was shown to bring good healing effects, if 0.2–0.4 mg/l water is applied. Filtering with active charcoal cleans the water after an exposition of the fish for 3–5 days at around 20–23 °C.

Letality

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *letal* = deadly.

This term describes the amount of dead victims due to an infection in relation to the total sum of infected persons/animals.

Lethality

Number of dead individuals in relation to sick people.

Leuckart, Friedrich Andreas Sigismund (1794–1843)

Heinz Mehlhorn
 Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Rudolf Leuckart (Fig. 1) was a German physician and zoologist, who was Professor for Zoology at the University of Giessen (at a time when also the famous chemist **Justus Liebig** taught there). Later he became Professor for Zoology and Comparative Anatomy at the University of Leipzig. Leuckart worked on a broad spectrum of parasites,

e.g., on *Trichinella spiralis* and showed its transmission cycle in pigs as well as the life cycle of *Ancylostoma caninum* and the transmission of trematodes by stages in snails. His famous books “*Die menschlichen Parasiten und die von ihnen herrührenden Krankheiten*” (Vols. 1, 2) = engl. “*The human parasites and the related diseases*” presented combined knowledge on parasites being important for veterinarians, human physicians, and zoologists at the same time (Fig. 1). Thus he created the basis for the new research field **Parasitology** as an own science line. Therefore he was selected by the German-Swiss-Austrian Society of Parasitology as a symbol. The awarding of the **Leuckart medal** honors researchers in any field of parasitology (Fig. 2).

Leucochloridiomorpha lutea

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This small, up to 2 mm long digenean trematode (family Brachylaimidae) is a common parasite of the bursa fabricii of ducks. First intermediate hosts are *Viviparus* sp. snails, which release furcated cercariae. These cercariae enter exclusively male snails of the same species, where they develop inside the testes into metacercariae. If this snail is ingested by ducks, the life cycle is completed.

Leucochloridium macrostomum

Syn. *L. paradoxum*. ► [Digenea](#). The colourful sporocysts of this trematode of the ► [cloaca](#) of

Leucochloridium macrostomum, Fig. 1 The tentacles of this amber snail are filled each with a metacercaria of the trematode, which initiates active movements, thus attracting the final hosts (birds)

birds enter the tentacles of their vector snail, form ► [cercariae](#) and metacercariae (Fig. 1), which pulsate, and thus attract the final host (► [Behavior](#)).

Leucochloridium Species

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The name comes from Greek *leukos* = white, *chloros* = slightly green. Tiny digenetic trematodes reaching about 1.5–2.6 mm in length and 1.2–1.4 mm in width. Their eggs are also very tiny (~24–30 µm × 16 µm) and are excreted within the feces of birds (e.g., tits, other singing birds). The adults are hermaphrodites and live attached at the cloacal wall of their hosts. The excreted eggs are ingested by so-called amber snails (*Succinea*

putris) living in terrestrial biotopes. Inside the snail's gut a miracidium larva hatches from each egg and transforms into a sporocyst, inside which infectious cercariae are formed. The whole brood sacs containing the sporocysts or their protruding ends penetrate into the snail's tentacles and initiate there strong pulsating movements which attract attention of the final hosts (birds). This induced pulsation is interpreted by some scientists as "active" manipulation of the parasite in order to enhance its chances to reach the final host and thus to become an adult worm.

In Europe two common species are found among others:

- *L. paradoxum* (1.5–1.9 mm × 1.0–1.3 mm); their brood sacs inside the snails are green-banded.
- *L. pertubatum* (2–2.6 mm × 1.4 mm); their brood sacs appear brownish-banded.

Leucocytozoon simondi, Fig. 1 Life cycle of *Leucocytozoon simondi* in its vertebrate hosts (domestic and wild ducks and geese) and in its vector (► *Simulium* spp. blackflies). 1–5 Sporozoites injected by the *Simulium* fly are carried by the bloodstream to the liver, where they enter Kupffer cells and form the multinucleate first-generation schizonts. The latter give rise to small merozoites (5) which may reinfect other hepatic cells (2) or invade lymphoid cells (6–8) or erythrocytes (9.1). 6–8 After invasion of lymphoid cells or macrophages, 4–6 days after infection, large schizonts (megaloschizonts) of

60–150 µm diameter are formed, which via cytomeres (7) produce numerous merozoites (8). 9–12 Having entered lymphoid cells, the majority of merozoites probably develops into gamonts (9.2), but it is thought that some may initiate further asexual reproduction. During the formation of the finally elongate or ovoid gamonts (20 × 5 µm), the host cells become distorted and appear elongated spindle shaped (10.2). Occasionally, spherical gamonts appear (10.1) which are thought to originate from hepatic merozoites (5) that have penetrated erythrocytes instead of lymphoid cells. However, there is no evidence

Leucocytozoonosis

Disease due to ► *Leucocytozoon simondi* in domestic and wild ducks and geese transmitted by bite of *Simulium* spp. (North America, Central Europe). *L. smithi* is found in turkeys in Europe. *L. (syn. Akiba) caulleryi* is transmitted by ► *Culicoides* spp. and occurs also in red blood cells.

Symptoms

The most important symptom is anaemia, which may lead to death. Initial symptoms are: loss of weight, uncontrolled turning of the head, problems when moving, reduction of egg production.

Diagnosis

Microscopical analysis of Giemsa-coloured blood smears.

Treatment

Pyrimethamine plus sulfonamides as prophylaxis; in clinical cases: Furazolidon or pyrimethamin.

Leupeptin

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes an antimalarial toxin, which needs an uptake by a so-called plasmodial surface anion channel (PSAC).

Levineia

Genus of ► *Coccidia*, synonymous to ► *Cystoisospora*.

Levinseniilla

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of digenetic trematodes of the family Microphallidae that parasitize in the intestine of shore birds.

L

Leucocytozoon simondi, Fig. 1 (continued) that these differ functionally from the elongate forms. When the vector has sucked blood, the formation of gametes (11, 12) is initiated inside the gut, leading, after fertilization, to an extracellular ► *zygote* (13). 13–17 The immobile zygote is transformed into a motile ► *ookinete*, which enters the intestinal wall (15), migrates through the ► *cytoplasm* of a gut cell, and begins its transformation into an ► *oocyst*, situated between basal membrane and epithelial

cells of the gut (17). 18–20 Formation of multinucleate sporoblasts (18) which give rise to numerous sporozoites (19; *SP*). The latter are released into the body cavity and migrate to the salivary glands (20). These slender sporozoites are finally injected into the next host. *CY* cytomere, *DG* developing microgamete, *E* erythrocyte, *HC* host cell, *IE* intestinal epithelium, *L* lymphoid cell/macrophage, *N* nucleus, *NH* nucleus of host cell, *PV* ► *parasitophorous vacuole*, *SG* salivary gland, *SP* ► *sporozoite*

LF

Short for ► **Lymphatic filariasis**, disease due to infections with *Wuchereria bancrofti* or *Brugia malayi*. 120 million people are infected, 40 million with severe symptoms of disease; it is the world's leading cause of disability. ► **Filariidae**.

Name

Greek: *phtheir* = louse, *a* = non, *pteron* = wing.

Classification

Order of ► **Insects**.

Lice

Heinz Mehlhorn¹ and Günter Schaub²

²Fakultät für Biologie, AG Zoologie/Parasitologie, Ruhr-Universität Bochum, Bochum, Germany

General Information

The order Phthiraptera is subdivided into two sub-orders: ► **Anoplura** (bloodsucking lice) and ► **Mallophaga** (feeding on skin, keratinous substances of feathers and hairs, and dermal secretion fluids). Both groups show the following common features:

- They have very short antennae (often in grooves).

Synonyms

Phthiraptera

Lice, Fig. 3 Scanning electron micrograph of a female body louse and several eggs attached at clothes.

Lice, Fig. 5 Scanning electron micrograph of an egg of the human head louse (*Pediculus humanus capitis*). Note the pores at the operculum.

Lice, Fig. 4 Light micrograph of the head region of a head louse. Note the two lense eyes.

- They are always wingless.
- Their eyes are reduced; they are eyeless or have 1 or 2 ommatidia.
- Their feeding (on keratin or blood) always requires the aid of endosymbionts in mycetomes (which are transmitted to progeny).
- Their life cycle constantly proceeds ► **hemi-metabolous development**; the relatively large eggs are always attached to hairs, feathers, etc.
- All developmental stages stay on their hosts permanently; host-to-host transmission occurs by body contact.

Lice, Fig. 6 Photos of two females of head lice (left) with protruding eggs and a male (right). Note the claws at the feet, which are used to clutch at hair.

Lice, Fig. 8 Scanning electron micrograph of *Phthirus pubis*

Lice, Fig. 9 Light micrograph of two pig lice.

Members of the ► **Mallophaga** (Fig. 1b) are furthermore characterized by a head which is broader than the thorax and by visible chewing mouthparts, whereas the bloodsucking mouthparts of members of the Anoplura are hidden inside their short and stumpy ► **proboscis** (Fig. 1a,4).

Of the about 500 known species of the suborder Anoplura, only three species are ectoparasites

of humans: ► *Pediculus humanus capitis* (head louse), living in head hair; *P. humanus corporis* (body or clothing louse), occupying the clothes and visiting the body only to feed (Figs. 2–7); and ► *Phthirus pubis* (► **Crab Louse**), developing mainly in the hairs of the genital region, but regularly also colonizing the other coarse hairs of the head and body, e.g., the eyelashes (Fig. 8). These lice are highly host-specific, obligate parasites, spending their entire life cycle on the host, and only infesting humans and monkeys. Animal lice (Figs. 9–11) only occasionally attack humans (► *Haematopinus suis*). Lice are even common in cold water when parasitizing, e.g., seals. (► *Antarctophthirus*). Only *P. h. corporis* transmits rickettsial or bacterial diseases.

Life Cycle

For details of the life cycle of biting lice (Fig. 1b), see ► **Mallophaga**. In human lice (Fig. 1a), after a temperature-dependent embryonic development of about 8 days, the first

^aSome authors name this species *P. capitis*

^bAlso named *P. humanus*

instar nymphs (1 mm long) hatch and within 7–10 days after two additional nymphal stages, the adults. (The term larva is used by scientists in Central Europe, but the term nymph by other scientists.) The whole developmental cycle (egg to egg) lasts about 2–3 weeks. Bacterial and fungal symbionts, which are restricted to special organs (► [Mycetomes](#)) near the gut or ovaries and transmitted transovarially to the eggs, are necessary for larval development and adult reproduction.

Important Species

See Table 1.

Distribution

Human lice occur worldwide, clothing lice regularly in poor regions where people possess only one set of clothes. In the USA, white people are more frequently infested with head lice than

Afro-Caribbean people, probably because of the better adaptation of the claws of the lice to hairs which are round or oval in cross section, respectively.

Morphology

The relatively small, narrow head of lice has very short antennae (five segments), and eyes are strongly reduced to two big ommatidia. The mouthparts are hidden inside the head. The labrum ensheaths the four long, thin stylets made from the two maxillae, the labium and the hypopharynx, the latter containing the salivary channel, whereas blood is ingested through the tube formed by the maxillae. The thoracic segments are fused, and the short legs bear strong claws that are optimally adapted to the diameter of the hairs of the host and cling onto hairs or fibers. The ► **cuticle** is very tough. The *Pediculus* spp. (Figs. 3–6) are slender insects of about 2–4 mm length, much longer than wide. Males and females can be distinguished by the body and claw sizes, patterns on the thorax, the shape of the abdomen, and the sclerotized penis-like genitalia of males. *P. pubis* is about twice as long as wide and about 1.5–2 mm long. The eggs (so-called ► **nits**) are about 0.8–1 mm long and about 0.3 mm wide and glued onto hairs or cloth fibers. After eclosion of the nymphs, the eggs appear white and remain glued. Eggs of the genera *Pediculus* and *Phthirus* can be distinguished by the shape and the appearance of the pores on the ► **operculum**, those of *P. h. capitis* show similar pores as *P. h. corporis* (Figs. 3–7), but are more intensively glued to hairs. The pores (► **Aeropyls**) are needed for the oxygen supply of the embryo.

Crossbreeding of the 2 *Pediculus* spp. is possible (therefore regarded as subspecies by different authors), but both can be distinguished by their tibial lengths, habitat preference, i.e., cloth or hair, and temperature preference, 28–29 °C for head lice and 31–33 °C for clothing lice. The individual color is genetically determined, darker clothing lice occurring more often

in association with inuits and other dark-skinned humans.

Reproduction

Only *P. h. corporis* colonies breed in the laboratory after adaptation to feeding on rabbits. Other species are fed on volunteers.

Adults copulate shortly after emergence or at a later point in time. About 24 h after mating, ► **oviposition** begins. Females of *P. h. corporis*, *P. h. capitis*, and *P. pubis* live about 5, 3, and 4 weeks and lay about 300, 90, or 30 eggs, respectively. *P. h. capitis* prefers to deposit eggs singly onto hairs in the neck and behind the ears, *P. h. corporis* in clusters on the fibers of clothes, e.g., on the seams, and *P. pubis* lays several eggs on a single hair.

Transmission

Lice are transmitted by interhost contact and/or by shared use of combs, hats, clothes, etc. Usually less than 10 lice per person occur, but more than 20,000 *P. h. corporis* or several hundred *P. h. capitis* have been collected from one person.

Feeding Behavior and Transmission of Disease

Lice are attracted to the host by warmth and odors. They are permanent ectoparasites, capillary feeders who suck blood about every 2–3 h. The ingested blood is stored and digested by trypsins and chymotrypsins in a capacious anterior midgut, followed by digestion of peptides in the narrow posterior midgut, and formation of feces in the hindgut. The saliva causes itching and the resulting scratches secondary bacterial infections. However, louse feces usually induces the first irritations.

Only *P. h. corporis* can transmit classic epidemic typhus, ► **trench fever**, and louseborne

► [relapsing fever](#), but experimental transmission of the pathogens is possible using *P. pubis*.

Classical epidemic typhus is caused by *Rickettsia prowazekii* and transmitted only among humans by pathogens present in the deposited feces (Fig. 2). These pathogens invade through skin lesions or are inhaled. The pathogens are infective in the feces for up to 3 months. The disease is prevalent in Europe, Africa, and South America, but incidence is declining.

Trench or 5-day fever, occurring in Europe, is caused by ► [Rochalimea quintana](#), showing a mode of transmission similar to that of typhus.

Louseborne relapsing fever is caused by ► [Borrelia recurrentis](#) and transmitted by crushing infected lice between the fingers or teeth. Thereby, bacteria present in the hemolymph or intestinal tract can invade skin lesions or the mucous epithelia. This disease occurs in Europe, Africa, South America, and Asia, but not in Australia.

Interaction of Vector and Parasite

If the lice suck blood within the first 10 days of illness, *R. prowazekii* is transmitted and multiplies in the lumen of the gut, but also in the cells of the intestinal wall. *R. prowazekii* is pathogenic to lice due to the destruction of gut cells. In the other bacterial infections, no pathogenic effects on the vectors are reported.

B. recurrentis invades the hemocoel of the insect about 4 days after ingestion, slowly multiplying there.

Diagnosis

By regular macroscopic control of hairs for the white eggs, the head- and crab lice, and by use of a fine-toothed comb, the head lice can be detected. In cases of itching of the skin of head and genital regions, a careful control for nits or lice

should be performed. In heavy infestations with *P. h. corporis*, skin is darkened and hardened (*morbus errora*), and in *P. pubis* infestations bluish spots (*maculae caeruleae*) develop, since these lice prefer to bite repeatedly in the same places. In the latter infestations, black spots of louse feces also occur in the underwear.

Control

Information beginning with the parents of children in kindergarten and school can strongly reduce the infestations. However, it should be pointed out that usually more than one member of a household is infested.

All lice can be killed using insecticides either as powder (clothing lice) or in lotions or shampoos (head- and crab lice). Malathion, carbaryl, and pyrethroids are used. Lotions left for some hours on the hair are more effective than shampoos. During the last years, head lice have occurred more often, especially on young children, mainly due to the attitude of some parents who do not wish to use insecticide lotions or shampoos. All stages of clothing lice are killed within less than 30 min at 50 °C, and within 1 min at 90–100 °C; using a tumble drier for 15 min and >60 °C is also sufficient. Exposition to –20 °C has not been investigated, but 24 h should be sufficient for killing. Since lice show a relatively weak starvation capacity, *P. h. capitis* and *P. h. corporis* will die after 3 and 4 days at 23 °C, respectively; for the latter, a storage of clothes for 17 days in a polythene bag is recommended. No vaccination is available (Insecticides, ► [Arthropodicidal Drugs](#)). However, appropriate neem extracts (WASH AWAY) clean the hair from lice.

Resistance

In several countries, lice are resistant to DDT, carbaryl, lindane, malathion, and in recent years also to permethrin or similar pyrethroids, while

those products, which suffocate the lice by covering or entering the tracheal spiracles, will not lead to resistance.

- are equipped with the smallest genomes among insects showing 108 Mb for females and 109 Mb for males. They are diploid organisms which possess in total six chromosomes and a telocentric one. Body lice show a guanine-cytosine (GC) content of 28 %. Thus these animals are unusually AT-rich. Inside the genome, no genes of prokaryotic origin occur so that it can be concluded that the obligatory symbiont *Candidatus Riesia pediculicola* does not transfer genes to its host. Although the genome of lice is very small, it shows full function and shares inner homology. Eighty percent of their genes are orthologous to other sequenced insects.
- While in eukaryotes the single mitochondrial chromosome appears typically circular (with a length of about 16 kb and 37 genes), in lice the 37 mitochondrial genes are located on 18 minicircular chromosomes. These minichromosomes of lice are 3–4 kb in length and contain each 1–3 genes. In lice, apparently recombination occurs between the minichromosomes being facilitated by the fact that identical sequences are present on different minichromosomes. Besides these 18 minichromosomes, several types of chimeric minichromosomes had been documented.
- Genetic data show that morphological and behavioural differences between head and body lice are probably results of epigenetics, which are due to other processes than changes in the underlying DNA-sequences. Thus in conclusion several authors claim that head and body lice are ecotypes of the same species. They differ with the exception of a single gene only in the expression and not in gene content. It might be speculated that different expression has started when humans reduced their body hair and started to wear clothes. In any way the three clades of lice are genetically nearly identically, but not in behavior, morphology, and physiology. Apparently several genes might have stopped action.

Linguatula serrata

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Name

Latin: *lingua* = tongue, *serratus* = sawlike.

Linguatula serrata, Fig. 1 Anterior end of an adult of *Linguatula serrata*

Linguatula serrata,**Fig. 2** Life cycle of *Linguatula serrata*.

1 Adults live in the nose of dogs (and rarely of man). 2 Embryonated eggs are set free via nasal mucus and/or feces. The thin outer eggshell is left out in drawings, since it disappears soon. 3 If intermediate hosts swallow eggs, the four-legged primary larva hatches and migrates via blood vessels to the inner organs. Humans may also become accidental intermediate hosts. 4–11 Larval stages 2–11 are included in a capsule of host origin and grow after molts. When final hosts ingest raw (or uncooked) meat of intermediate hosts, the adult stages develop inside the nasal tract. Infected humans suffer from the ► [Halzoun syndrome](#). AN annuli, B bore organ, EX extremity with a claw, MK mouth hooks, IN intestine, LA primary larva, M mouth, SH inner eggshell, TH thorns

**Classification**

Species of ► [Pentastomida](#).

Morphology

Females grow up to 13 cm, while males reach only 2 cm. Both live inside the nasal system of meat-eating mammals (including dogs, man). They keep attached at the wall of the respiratory system by means of their mouth hooks (Fig. 1). Females excrete thousands of (up to 5,000,000) eggs per

day. These stages are infectious for plant feeders (including humans), where the larva take them into different organs away from the intestine. If these larvae are eaten by the final hosts, the larvae invade the nasal system and reach maturity within 6–7 months and live for about 15 months (patency period).

Disease

Halzoun Syndrome or Marrara syndrome are the human diseases described as infection of man,

who can be the final host (with worms in the nose) and intermediate host (with encapsulated larvae in inner organs). The symptoms are nasal infections, blocking of breathing, edema, but also deafness in case of infections with adult worms. In cases of encapsulated larvae, these symptoms depend on the infected organ.

All major classes of lipids found in free-living organisms are also essential biochemical

Lipids, Fig. 1 Generalized representation of the central pathways for *de novo* biosynthesis of lipids by parasites. Boxed substrates are obtained from the host. Pathways present in the mammalian host, but absent in most parasites, are represented by dotted arrows. For instance, few of the parasites studied appear capable of *de novo* biosynthesis of fatty acids. Abbreviations: *DAG* diacylglycerol, *CDP-DAG* cytidine diphosphodiacylglycerol, *DOXP*

1-deoxy-D-xylulose-5-phosphate, *Farnesyl PP* farnesylpyrophosphate, *GAP* glyceraldehyde-3-phosphate, *Geranyl PP* geranylpyrophosphate, *Geranylgeranyl PP* geranylgeranylpyrophosphate, *HMG-CoA* hydroxymethylglutaryl-CoA, *IPP* isopentenylpyrophosphate, *TAG* triacylglycerol, *PA* phosphatidic acid, *PC* phosphatidylcholine, *PE* phosphatidylethanolamine, *PI* phosphatidylinositol, *PYR* pyruvate

constituents of parasitic protozoa and helminths. Lipid metabolism in parasites has several unique features and the content, distribution, and requirement of lipids and the synthetic capabilities for these substances show considerable variation between different parasite species. In addition, profound modifications in the lipid composition may occur during differentiation and maturation of a parasite and even in a specific stage, and rearrangements in lipid composition may be central to avoid host defence mechanisms. In addition to their common functions, lipids in endoparasites may be associated with adaptive mechanisms to parasitism. For example, in schistosomes the outer bilayer of the tegumental membrane complex contains lipids which have been suggested to play a major role, through inducible modifications, in modulating the host's effector mechanisms of immunity and in parasite survival. Since lipid metabolism in endoparasites is characterized by substantial limitations of both

synthetic and catabolic capabilities, these organisms seem to selectively absorb lipids from the host's diet with subsequent incorporation of these substances into their species- and stage-specific lipid pattern.

In most organisms the oxidation of fatty acids is an important source of ATP. This is, however, not the case in most parasites. In the majority of protozoa and in adult helminths, utilization of lipids as an energy source is either very limited or not feasible at all (Fig. 1). The reason for the absence of a functionally active β -oxidation in those parasites where all the enzymes involved in this process are present, is unclear. A possible explanation for this deficiency could be that sufficiently effective terminal oxidative processes are lacking in most parasite cells and tissues, in particular the tricarboxylic acid cycle and a cytochrome oxidase-linked respiratory chain, for oxidation of reduced coenzymes accumulating in large amounts during fatty acid degradation.

Thus, the role of the β -oxidation enzymes of protozoa and helminths remains unclear, but their action may be associated with biosynthetic processes, such as fatty acid elongation or the formation of volatile fatty acids from carbohydrates. However, some protozoa seem to possess the ability to catabolize lipids to carbon dioxide and water, but even if it occurs, this process is not a significant source of energy. Amongst the helminths, such marked oxidative capacities appear to be restricted to some larval parasitic and most free-living stages.

In accordance with their opportunistic way of living, parasites usually have very limited biosynthetic capacities. Whenever possible they obtain substrates for the synthesis of their structural elements from the host. Most parasites indeed acquire the vast majority of their lipids from the host. Protozoan parasites and helminths are generally unable to synthesize fatty acids *de novo*. However, in common with other organisms, many parasites have the ability to desaturate or to lengthen the chains of fatty acids absorbed from their habitat by the sequential addition of acetyl CoA as two-carbon unit (Fig. 1). Trypanosomatids and apicomplexan parasites can synthesize fatty acids *de novo* using the type II fatty acid synthase (FAS II) machinery found in prokaryotes and plants. This system is composed of multiple proteins rather than being a multifunctional enzyme complex as in higher animals, is membrane-associated rather than cytosolic and is sensitive to the naturally occurring antibiotic thiolactomycin. Surprisingly, *T. brucei* uses mainly, instead of the FAS II system, 3 microsomal elongases in a consecutive way for the stepwise synthesis of fatty acids, for instance in the bloodstream stage for the synthesis of myristate, which is required for the synthesis of GPI anchors in larger amounts than the host can provide.

In trypanosomes, acetyl CoA used in fatty acid elongation is preferentially derived from threonine via a pathway involving threonine dehydrogenase and glycine acetyltransferase. Trypanosomatids are also able to desaturate

exogenously supplied fatty acids. Most deficient in lipid metabolism are the anaerobic protozoans, including *Giardia*, amoebae and trichomonads, which cannot synthesize fatty acids, cholesterol, and other sterols from acetate or mevalonic acid. They are also unable to employ fatty acids as energy source, nor are they able to elongate, shorten or desaturate fatty acids. However, they possess the capacity to remodel the fatty acid composition of their phospholipids.

Fatty acids, which are absorbed by parasites from exogenous sources, are rapidly incorporated into their triacylglycerols and phospholipids (Fig. 1), and the pathways responsible for these processes appear to be similar to those found in other animals. Most parasites appear able to manufacture phosphoglycerides and sphingolipids via *de novo* synthetic pathways, provided they have access to suitable precursors, such as fatty acids and sugars. Activation of fatty acids to acyl CoA thioesters is catalyzed by acyl CoA synthetase, which is widely found in parasites. The routes involved in the subsequent steps of synthesis and interconversion of complex lipids are, like the initial step, also similar to those present in higher animals (Fig. 1).

Although sterols, such as cholesterol, are not synthesized *de novo* by parasitic helminths, they do possess a mevalonate pathway (Fig. 1). In most helminths as well as parasitic protozoa, this mevalonate pathway is active and is used for the biosynthesis of dolichols for protein glycosylations, of quinones as electron transporters in the respiratory chain, and of farnesyl and geranylgeranyl pyrophosphates as substrates for the isoprenylation of proteins. Cestodes and trematodes also excrete isoprenoids that act as hormones in the development of insects, notably ecdysteroids. In contrast to helminths, trypanosomatids can synthesize sterols *de novo*. However, they do not synthesize cholesterol, but instead synthesize ergosterol-related sterols, by a biosynthetic pathway similar to that operating in pathogenic fungi, a finding that explains the sensitivity of these protozoans to particular antimycotic drugs, such as ketoconazole. The

bloodstream stages of African trypanosomes cannot synthesize sterols and have to acquire host cholesterol to meet their sterol requirements. A unique feature of apicomplexan parasites is the utilization of a mevalonate-independent route for the biosynthesis of isoprenoid precursors found in many prokaryotes and in the plastids of plants (Fig. 1). In *Plasmodium* and related parasites, this 1-deoxy-d-xylulose-5-phosphate (DOXP) pathway is located within the apicoplast, and because it is not present in the host it provides several attractive targets for chemotherapy.

Several unique lipid structures and pathways have been identified in parasites. A peculiar class of triacylglycerols, which contain esterified volatile fatty acids (2-methylbutyrate, 2-methylvalerate, *n*-valerate), occurs in *Ascaris suum* and a few related nematodes, where they are especially abundant in the eggs. The fatty acids are end products of carbohydrate metabolism in the nematode's muscle tissue and then transported to the ovaries where they are incorporated into triacylglycerols. During egg development, the volatile acids are enzymatically released from the fat storage and serve as an energy-rich fuel for the larval parasite. In nematode eggs, long-chain fatty acids, which also derive from triacylglycerols, are utilized for the resynthesis of carbohydrates through a functional, glyoxylate cycle. The presence of this pathway in developing eggs of some helminths is unusual, as it does not occur in most other animals. A characteristic feature of trypanosomatids is that the entire machinery for the synthesis of ether lipids from glycerol and fatty acids is associated with the glycosomal compartment of the cell. Another unusual feature of many helminths is the presence of the lipid rhodoquinone instead of ubiquinone as a functional constituent of anaerobically functioning mitochondrial respiratory chains in eukaryotes, and it is remarkable that they can synthesize this electron carrier *de novo* (Quinones). In general, parasites have retained only those biosynthetic pathways that are required to modify lipids obtained from the host. Lipids (such as fatty

acids and cholesterol) are obtained from the host, but the lipids that are more difficult to acquire because of their low concentration in the host are synthesized by the parasite, usually by modification of more abundant lipid substrates. Other examples of these important unique lipid structures, such as the glycosylphosphatidylinositol anchors and the lipophosphoglycans, are discussed separately.

Lipophosphoglycan

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Lipophosphoglycan (LPG) is the dominant cell surface glycoconjugate of ► *Leishmania* promastigotes. In these protozoan stages, approximately three to five million copies of LPG together with glycoprotein molecules (mainly the promastigote surface proteinase) protrude above a dense cell surface ► *glycocalyx* of about ten million copies of glycosylinositolphospholipids (► *Glycosylphosphatidylinositols*). The molecule consists of four distinct domains, some of which are highly unusual for a eukaryotic glycoconjugate (► *Glycosylphosphatidylinositols*, Fig. 2). This includes the means of membrane anchoring by phosphatidylinositol-linked C₂₄ or C₂₆ saturated hydrocarbons, a core heptasaccharide, a repeating phosphorylated saccharide backbone containing a unique 4-*O*-substituted mannose, and a terminal neutral oligosaccharide. While the lipid anchor of LPG is highly conserved, the glycan composition shows extensive variability among different *Leishmania* spp. stages and strains, the most striking of which is the increase in size of the phosphorylated saccharide domain as displayed by metacyclic stages. The distinctive structural features of LPG and its developmental modification implicates

important functions for this molecule, including attachment of the parasite to the sandfly vector midgut epithelium and adhesion and entry into the host macrophages.

Lipoptena

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Genus of louseflies (e.g., *L. cervi*, *L. capreoli* of small ruminants, and wild deer), reaching a length of about 5 mm. ► [Hippoboscidae](#), ► [Diptera](#), ► [Keds](#). The females get rid of their wings after reaching a host. Thus on cervids only wingless stages are seen (Fig. 1). These specimens may also attack humans, where both sexes start bloodsucking, which leads to itching. During their lifespan of 5–6 months, the females produce 10–15 larvae 3 (like tsetse flies), which start pupation when laid on soil. The pupae are brownish red. After about 20–23 days, the adults hatch from the eggs, copulate 4–5 days later after starting bloodsucking on a host, which was reached by help of their wings.

Lipoptena, Fig. 1 Scanning electron micrograph of the anterior aspect of *L. cervi*. Note the large claws for attachment along the hair

Lister, Joseph, Lord (1827–1912)

English scientist, discoverer of antisepsis.

Listeria

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Gram-positive bacteria, which may be transmitted by bites of argasid ticks or fleas but mainly by ingestion of contaminated food (syn. *Listerella*).

Listeriosis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Sir Joseph Lister (1827–1912), English surgeon, described this species of bacteria. The agents of listeriosis (*Listeria monocytogenes*) are transmitted by contact with infected animals, by contaminated food, or during bites of ► [fleas](#) or argasid ticks.

Listrophorus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of mites of the family ► [Demodicidae](#). *L. gibbus* infects rabbits.

Litomosoides

Classification

► Nematode, ► Filariidae.

General Information

The adults of *L. carinii* (♀ up to 7 cm ♂ 2.8 cm in length) live in general in the pleural cavity of *Sigmodon* rats. However, occasionally they occur also in the eyes of their hosts (Fig. 1). The females produce sheathed microfilariae, which reach a length of 90–120 µm and occur all day in the blood. Blood-sucking mites (*Ornithonyssus*) take up such L₁, which grow up to the infectious L₃ inside the mite. During blood sucking the transmission occurs and the worms reach maturity within 50–80 days.

Diagnosis

Giemsa-stained blood smears.

Therapy

Ectoparasitocidal drugs, diethyl-carbamazine against microfilariae.

Litomosoides, Fig. 1 Macrophoto of an eye of a cotton-rat containing an adult worm of *Litomosoides carinii*

Litomosoides carinii

Synonyms

L. sigmodonti.

This nematode species which is kept in laboratory animals (*Mastomys*, *Sigmodon*) that are imported from desert regions and reared in laboratories, lives in the pleural cavity of mice. The males reach a length of 2.8 cm, the females grow up to 7 cm and are mostly found in coiled crowds (like the other members of the family Onchocercidae). The females produce many sheathed larvae (microfilariae) with a length of 90–120 µm. They are found in the blood, from where they are taken up by bloodsucking mites (► *Bdellonyssus*, *Ornithonyssus*). After two molts the larvae 3 are injected into the mammal during the next blood meal. The adult may also occur accidentally in the anterior chamber of the rodents (Fig. 1). **Prepatent period:** 70–80 days; **Patency** 1–3 years. This worm is used in laboratory as model to develop onchocercidal drugs.

Litomosoides carinii, Fig. 1 Macrophoto of the eye of a jird (*Meriones* sp.), within which an adult female is accidentally seen

Classification

► Nematodes, ► Filariidae.

Life Cycle

Figures 1, 2, and 3; ► Filariidae.

General Information

This worm is found in Africa between 10° North and 5° South. The female adults reach a length of up to 7 cm and a width of 0.5 mm, while the males are smaller (3.2 cm × 0.4 mm). It is characteristic that the adult worms wander throughout the subcutaneous tissues and may appear in the anterior

***Loa loa*, Fig. 3** (A) Stages in humans: 1, Adult in the eye chamber; 2, microfilaria in the blood (= L₁); 3 tail of microfilaria. (B) Stages in vector (*Chrysops*): 4, larva 2; 5, larva 3; 6, larva 3 penetrating into the skin during bloodsucking of *Chrysops* specimens. After molt to larva 4, molt to adult occurs. A anus, AI anlage of intestine, E erythrocyte, EP epidermis, IN intestine, MF microfilaria, N nucleus, SH sheath

chamber of the eye (Fig. 1). The microfilariae live in the blood and appear most often between 10 am and 1–3 pm in the peripheral blood. The vectors are biting flies and tabanids) of the genus ► *Chrysops*, within which the L₃ is developed.

Diagnosis

Microscopy of Giemsa-stained blood smears showing the unsheathed microfilariae (Fig. 2) (► [Loiasis](#)).

Loa loa: Genomics

Desjardins et al. (2013) described that the genome of *Loa loa* has a size of 9.4 Mb and predict the existence of 14,907 genes on the basis of microfilarial RNA sequencing. The *Loa loa* genome encodes many immunological relevant genes as well as protein kinases. Despite lacking *Wolbachia* bacteria *L. loa* does not show new metabolic synthesis or transport systems compared to *Wolbachia* bearing filariae.

Local Adaptation

Aubry reports that in 1895, when French armies conquered Madagascar, 5,756 soldiers died during the campaign: 25 died from injuries, the 5,731 others died from local parasitic diseases, mainly ► [malaria](#). Such an event (many others could be reported) means that autochthonous human populations are usually better adapted to resist local parasitic diseases than are allochthonous invaders.

This example illustrates an old question, that of “local adaptation,” which has been recently the subject of active debates. The question is: which one (the host or the parasite) is locally better adapted to the other?

If the host is better adapted, this means that its defenses are more efficient against local populations of the parasite than against foreign populations (in this case, the reproductive success of the parasite is better in allochthonous than in autochthonous populations of the host). This case is illustrated by the French army in Madagascar.

If the parasite is better adapted, this means that its fitness (reproductive success) is better in local populations of its hosts than in foreign populations. This case is illustrated by many experimental studies. For instance, Xia et al. demonstrate, both by miracidial exposure and microsurgical transplantation of larval stages

(sporocysts), that ► *Schistosoma japonicum* develops significantly better in local populations of the intermediate snail host *Oncomelania hupensis* than in populations of the same species collected at another place 1,000 km away. In particular, histological observations show that rejection of grafts is significantly more frequent in allopatric than in sympatric combinations.

Various genetical models predict that better local adaptation of the parasite should be the rule: parasites should stay closer to “optimal virulence” in sympatric populations of hosts than in allopatric ones. This prediction seems to contradict the example cited above of the susceptibility of human populations to allochthonous diseases. In fact, the contradiction is only apparent, because “better adapted” does not mean “more virulent”: the dramatic pathogenicity of *Plasmodium falciparum* in European invaders certainly provided less opportunities for transmission than a more lasting disease, so that the parasite, although less virulent, was better adapted to local human populations.

Locomotory Systems

All ► [Protozoa](#) are motile in at least one stage of their life cycles. During their evolution, the different species have developed distinct locomotory systems such as ► [pseudopodia](#) (e.g., ► [Amoeba](#)), ► [flagella](#) or ► [cilia](#). The invasive stages of sporozoans, i.e., the merozoites and sporozoites, have three types of movement: gliding, twisting, and bending (► [Coccidia](#), motility). Only the first of these leads to active displacement of the organisms; the other two only change the direction of movement. The gliding form of movement is extremely rare in eukaryotic cells. It is temperature-dependent and cytochalasin B-sensitive, the latter property suggesting the participation of ► [actin](#) in the process. The gliding movement may be related to the ► [capping](#) phenomenon in sporozoans. In capping, the organisms aggregate materials on their surfaces and move them towards the posterior pole, from where they release them into the surroundings. A parasite floating in a liquid could move forward

using this type of action. The most studied of the capping phenomena is the circumsporozoite reaction of *Plasmodium falciparum* sporozoites (► [Micronemes](#)).

Löffler Syndrome

Hemorrhages and inflammation foci within lungs of humans during the migration phase of larval ascarids (► [Ascariasis](#), [Man](#)) being accompanied by dyspnea, slight fever, blood ► [eosinophilia](#) plus coughing.

Löffler, Friedrich August Johannes (1852–1915)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Friedrich Löffler was a German physician and a bacteriologist and later a professor at the University of Greifswald. During the years 1879–1884, he was the assistant of Robert ► [Koch](#) at the Imperial Health Office in Berlin. He became famous due to important discoveries, such as in the year 1894 the determination of the agent of diphtheria (*Corynebacterium diphtheriae*), the virus of food-and-mouth disease of cattle (*Aphthae epizooticae*) together with Frosch, the agent of malleus (*Pseudomonas mallei*) of horses and carnivores together with Schütz (1882), and the agent of erysipelas (*Erysipelothrix rhusiopathiae*). The German Löffler Institute founded in 1910 at its main seat on the Isle of Riems (near Greifswald) and five other dependences in German towns represent today the Central German Institute for Virus Research and register officially all new products on veterinarian immunodiagnostics.

Löffler's Lung Infiltration

Clinical symptom due to infections with ► [Ascaris](#), ► [hookworms](#), ► [Strongyloides](#), ► [Paragonimus](#).

Loiasis

Synonyms

Eye worm disease.

Loiasis results from an infection of the subcutaneous and deep tissues with adult ► [Loa loa](#), transmitted by a biting fly (► [Chrysops](#); ► [Filariidae](#)). Larvae enter at the site of the fly bite and slowly develop into adults. Adult worms make their appearance after a year or more, when they give rise to symptoms during their subcutaneous or subconjunctival migration (► [Eye Parasites](#)). The living worm is not inflammatory, but dead worms give rise to microabscesses (► [Abscess](#)) with eosinophils. The released microfilariae circulate in the blood and when they die elicit small granulomas with epithelioid and giant cells; these may give rise to symptoms referable to many organs, including the brain.

Main clinical symptoms: Swellings (so-called calabar-swellings) of the skin = ► [oedema](#) of skin, passage of worms through the eye.

Incubation period: 2–12 months.

Prepatent period: 6 months–4 years.

Patent period: 4–17 years.

Diagnosis: Microscopic analysis of blood smear, ► [microfilariae](#) are found at 1–5 clock p.m. in the peripheral blood, ► [Serology](#), ► [Loa loa](#), Fig. 1.

Prophylaxis: Avoidance of *Chrysops*-bites in West Africa.

Therapy: Treatment see Nematocidal Drugs, surgical removal of the worm, when passing the eye.

Longevity, Longvivity

The lifespan reached by larval and adult parasites is species-specific (short: hours – miracidia; weeks – *Enterobius* or long: months – female mosquitos, ► [fleas](#); years: tapeworms, schistosomes, hookworms).

Long-Lasting Insecticidal Nets

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term describes mosquito nets consisting of rather strong fibers being impregnated with quick-acting insecticides (e.g., pyrethroids), which repel or kill mosquitoes on contact and thus prevent them from biting for up to 3 years.

Loop

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Loop mediated isothermal amplification is a method to detect ► [Ehrlichia](#) infections.

Looss, Arthur

German parasitologist (Fig. 1), died in 1923, discoverer (1900 in Cairo) of the transmission of the hookworm infections.

Looss, Arthur, Fig. 1 Photo just prior to his death in 1923. His great discovery was the transmission of the hookworms

Loperamid

Drug that stops diarrhoea; it is also active against acanthocephalans (e.g., ► [Macracanthorhynchus hirudinaceus](#)).

Lophomonas

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of hypermastigid flagellates in the intestine of cockroaches possessing several thread-like ► [axonemes](#) and two deeply embedded spiral bands bearing single flagella.

Loss in Performance

The parasitic load often introduces considerable reduction of the fitness of hosts, i.e., they look tired, their skin is pale, their hairs appear dull, their movements are slow, and they grow slowly if at all. Thus several female birds clearly prefer bright, shining, and highly active male mating partners that indicate health.

Louping Ill

Louping ill is a sheep disease found in North Britain which is caused by the LI virus (► *Flavivirus*, group B). It is transmissible to human beings in close contact with sheep (laboratory workers, sheep farmers, veterinarians, and butchers), or those exposed to tick bites; at least one human death has been proven.

Louse Flies

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Synonyms

Hippoboscidae; Keds.

These flies received their trivial name from people's observation that they live like true ► *lice* in the hair of their hosts after having infested a host and discarded their two wings. Their thorax is equipped with strong legs armed with thick claws. The horse louse fly ► *Hippobosca equina* reaching a length of 8 mm preserves its wings. The deer louse fly *Lipoptena cervi*, which measures 3–5 mm in length, keeps the wings as males,

while females lose them. The sheep louse fly *Melophagus ovinus* (~5 mm long), which is also erroneously named “sheep tick”, has in both sexes completely reduced wings and is transmitted during body contacts. Both sexes suck blood on the surface of their hosts. Their bites are painful and lead to loss of body weight of the hosts and hair loss. Females discharge already larvae 3, which start pupation during the next 10 h. The pupal cocoon appears reddish brown and is glued to the hair. During their life span of about 4–7 months, females produce up to 15 larvae.

Louse-Borne Spotted Fever

Human disease due to infection with ► *Rickettsia prowazekii* being transmitted by the feces of ► *lice*.

Systematics

Members of several families of the class ► **Secernentea** (► **Phasmidea**) of ► **Nematodes**, *Dictyocaulus* (Fig. 1).

Lung Worms, Fig. 1 Life cycles of several lung worms of different hosts. (a) *Dictyocaulus* spp. (large lungworms, see Table 4.1). (b) ► *Protostrongylus* spp. (small lungworms; see ► **Nematodes**, Table 1). (c) *Crenosoma striatum* (male 5–7 mm, female 12–16 mm long). (d) *Metastrongylus elongatus* (syn. *M. apri*: male 15–25 mm, female 20–55 mm long). 1 Fully embryonated eggs (D) or first-stage larvae are excreted with saliva and/or feces of final hosts. 2, 3 In *Metastrongylus* spp. (L₁ in eggs), in *Protostrongylus* spp. (as in ► *Muellerius* spp., *Neostrongylus* spp.), and in *Crenosoma* spp., the L₁ is ingested by intermediate hosts (earthworms or various species of land-living snails), inside which the sheathed third larval stage (L₃) is formed via two molts. *Dictyocaulus* spp. do not need an intermediate host but

develop free-living L₂ and L₃, which are ensheathed by the molted cuticles of the preceding larval stage. 4 The infection of the final hosts occurs by oral uptake of free larvae (L₃) on top of grass blades or by eating infected intermediate hosts with forage. Ingested larvae enter the intestinal wall at species-specific sites, penetrate lymph nodes, molt there, and thus become larvae of the fourth type. The L₄ larvae enter the heart via the bloodstream, thus reaching the lung, and passing into the bronchial and tracheal cavities, where it becomes mature (after another molt). If L₃ larvae are taken up late in the year, their development proceeds until the preadult stage, then it stops, and they hibernate, reaching maturity in early spring (► **Hypobiosis**). E esophagus, L_{1–3}, larval stages, SH ► **sheath** (formed by larval ► **cuticle**)

Life Cycle

See Figs. 1, 2, and 3.

Species

These nematodes parasitize inside the trachea, bronchioles, and/or in the lung alveoles of their hosts which belong (depending on the species) to many groups of vertebrates. There is distinguished between **large** and **small lung worms** (Figs. 1–5).

Very important genera are:

- *Aelurostrongylus abstrusus*
- *Angiostrongylus vasorum*
- *Bronchiostrongylus* species

- *Capillaria* species
- *Crenosoma* species
- *Cystocaulus* species
- *Dictyocaulus* species
- *Elaphostrongylus* species
- *Filaroides* species
- *Metastrongylus* species
- *Muellerius* species
- *Neostongylus* species
- *Otostrongylus* species
- *Protostrongylus* species
- *Troglostrongylus* species
- *Varestrongylus* species

Lyme Disease

Andrew Spielman¹ and Heinz Mehlhorn²

¹Department of Tropical Health, Harvard School of Public Health, Boston, MA, USA

²Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The name Lyme came from the little town in USA, where many cases were first noted and where the first ► *Borrelia burgdorferi* bacteria were isolated.

Other names for this disease are tick-borreliosis (► ticks as vectors of human diseases).

After a bite of an infected *Ixodes* tick the three phases of disease with the following symptoms may occur:

1. **Within days up to 6 weeks:** Erythema migrans, myalgia, swelling of lymphnodes, apathy (Fig. 1).
2. **Within weeks to months:** Urticaria, diffuse erythema, meningitis neuritis, radiculitis, myopericarditis, arthritis myositis, myalgia, severe-sickness feeling, affection of the

Lyme Disease, Fig. 1 Typical *Rosacea migrans* = primary sign of Lyme-borreliosis

- respiratory tractus, osteomyelitis, pain during any movement, pareses (Fig. 2).
3. **Months to years:** Acrodermitis atrophicans, chronic encephalomyelitis, spastic paresis, mental disturbances, chronic arthritis, arthropathy, severe apathy.

Lyme Disease, Fig. 2 Face of child with a paresis of the Nervous trigeminus (Courtesy of Professor Ackermann, Cologne)

Diagnosis

Anamnesis: tick bite, erythema migrans (the latter occurs only in 70 % of the cases), serology.

Therapy

First-stage treatment: oral application of Doxycyclin, Ampilicin or Cefuroxim, later: i.v. Ceftriaxon.

Tick Bites, Ticks as Vectors of Human Diseases, ► [Borrelia](#).

Lymnaea

Snail species, vector of many trematodes, e.g., *Fasciola*.

Lymphadenosis Cutina Benigna

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Symptom of disease during infection with ► [Borrelia burgdorferi](#) transmitted by ► [Ixodes](#) species.

Lymphocytic Meningoradiculitis Bannworth

Symptom of phase 2 of ► [Lyme disease](#).

Lymphocytome

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This symptom of disease – also described as ► [Bäverstedt-syndrom](#) – occurs during an infection with a tick-borne borreliosis and appears as benign swelling of the skin at the breast nipples or earlaps.

Lynchia maura

Lousefly (► [Hippoboscidae](#)) of birds (synonym of = *Pseudolynchia*), e.g., *P. canariensis*.

Lysosomes

Lysosomes are vesicles measuring 0.2–0.5 μm and bounded by a single membrane. They are derived from the sER and are formed and released from the secretion side of the ► [Golgi apparatus](#) (the trans-side). They contain enzymes such as phosphatases, ► [proteinases](#), lipases, nucleases, etc. and have an internal pH of 4–5. When first released they are called primary lysosomes. After fusion with the endocytotic vesicles their enzymes become active and the vesicle is then called a secondary lysosome. In these secondary lysosomes, or phagolysosomes, the ingested food is dispersed (► [Endocytosis](#), Fig. 1B). Another type of secondary lysosome is the ► [autolysosome](#), which is involved in the disintegration of cellular waste material, thus providing the function of debris disposal. Defective lysosomes introduce diseases (e.g., mucopolysaccharidosis).

Lyssa

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Latin: rage, fury.

This term describes the symptoms of the ► [rabies](#), which occurs due to infections with viruses being transmitted during bites, e.g., of dogs and also by bats (► [vampire bats](#)).

Lyssavirus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Virus of the so-called rhabdovirus group introducing rabies disease.

See ► [blood-licking bats](#).

Lystropodia

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Genus of the family Nycteribiidae (bat louse-flies).

Lytta

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Name

Greek: *lytta* = fury.

This term describes an uncontrolled biting behavior of dogs that have ingested beetles belonging to the genera *Lytta* sp. or *Meloe*, which contain cantharidin that introduces this behavior.

M

M.I.F.C.

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Merthiolate-iodine-formaldehyde concentration (Fig. 1), method to concentrate parasitic stages (protozoans/worm eggs) from fecal samples using two solutions:

- (A) 250 ml aqua dest
 - 200 ml thimerosal (1:1,000 in aqua dest)
 - 25 ml formalin (40 %)
 - 5 ml glycerine
- (B) 5 % fresh Lugol's solution (7.5 g iodine potassium in 18 ml aqua des, plus 5 g iodine plus aqua dest ad 100 ml)

Prior to use, 4 ml **A** plus 1 ml **B** are mixed with 1 g feces, filtrated, and added with 7 ml cold ether.

M.I.F.C., Fig. 1 Zonation in the tube after centrifugation

After shaking, the solution is centrifugated for 5 min at 500–1,600 g. Then the zonation of Fig. 1 is obtained. The sediment is studied by means of light microscopy.

Macracanthorhynchus hirudinaceus

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

Classification

Genus of ► [Acanthocephala](#).

Species

M. hirudinaceus.

Name

Greek: *makros* = large, *acantha* = thorn,
rhynchos = mouth; Latin: *hirudo* = leech.

Life Cycle

Acanthocephala/Life Cycle.

Disease

This worm (female 60 cm, male 15 cm) is a parasite of pigs, where it reaches maturity (Fig. 1) and excretes the typical eggs (Fig. 2). In pigs the **prepatent period** is 8–12 weeks, the **incubation period** takes only 10 days; then the following **symptoms of disease** may be seen: enteritis, peritonitis, diarrhea, malnutrition, and abdominal pain. In humans, however, the worm does not reach maturity. It becomes attached with the hooked proboscis at the intestinal wall and may introduce even perforation (acute abdomen with peritonitis). The rather

Macracanthorhynchus hirudinaceus, Fig. 1 Adult *Macracanthorhynchus hirudinaceus* from pig

Macracanthorhynchus hirudinaceus, Fig. 2 Infectious eggs of *Macracanthorhynchus hirudinaceus* from feces of pigs

long worm leads to intestinal disturbances within 2–12 weeks (incubation period). The infection of humans and pigs occurs orally by uptake of infected beetles or parts of them (Fig. 3).

Diagnosis

In pigs: microscopical demonstration of eggs (Fig. 2); in humans: Röntgen-image analysis of the gut shows wall-attached worm larvae.

Macracanthorhynchus hirudinaceus,

Fig. 3 Diagrammatic representation of the lifecycle of the acanthocephalans of pigs and humans (*Macracanthus hirudinaceus*) and of ducks (*Polymorphus* sp.). 1 Final hosts; 2 Eggs in feces; 3 Intermediate hosts; 5–6 Development of the larval stages (Acanthella, Cystacanth), which grow up to adults in final hosts. *ac* acanthor, *H* hooks, *IP* inflammation region, *IW* intestinal wall, *PH* proboscis hooks, *RA* annulus

Therapy

Loperamid was shown to be efficacious in pigs; see ► [Acanthocephalacidal Drugs](#).

Macrobilharzia

A genus of giant schistosomes (up to 8 cm long) of birds, the cercariae of which may lead to dermatitis in humans, too.

Macrocytic Lactones

Group of different nematocidal drugs.

Macrofilariae

Adult male or female filariid worm. ► [Filaridae](#).

Macrogamete

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

In ► *Coccidia* gamogony proceeds as ► oogenesis, i.e., the female ► gamont grows without

any division to become a macrogamete. After fertilization by a microgamete, the ► wall-forming bodies of the macrogamete fuse below the fecundation membrane (Fig. 1; ► Cyst Wall Fig. 1).

Macrogamete, Fig. 1 Diagrammatic representation of a mature eimerian macrogamete (limited by two membranes, other species have only one). *AM* amylopectin, *DI* dense inclusion, *DWI* developing wall-forming body of type 1, *ER* endoplasmic reticulum, *FN* fingerlike protrusion of the active nucleus, *GO* ► Golgi apparatus, *HC* host cell, *HN* host cell nucleus, *I* inclusion in ► mitochondria, *IF*

intravascular folds, *IT* intravascular tubules, *LM* limiting membranes of the macrogamete, *LP* limiting membrane of *PV*, *MI* mitochondrion, *MP* micropore, *N* nucleus, *NU* ► nucleolus, *PV* ► parasitophorous vacuole, *ST* structures surrounding the active nucleus, *UL* underlying material, *WFI I II* wall-forming bodies of types I and II

Macrogametocytes

Stages (macrogamonts), that develop into ► [macrogametes](#) (female gametes), e.g., in ► [Plasmodium](#) spp. or in other ► [Coccidia](#).

Macronucleus

In ciliates, two morphologically distinct nuclei occur: a generative ► [micronucleus](#) and a somatic macronucleus (► [Nucleus](#), ► [Balantidium coli](#)), ► [Ichthyophthirius](#).

Macrophages

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Phagocytic cells of mammalian hosts, which engulf agents of diseases that have penetrated.

Macrophages, Fig. 1 Light micrograph of a macrophage containing several tachyzoites of ► [Toxoplasma gondii](#) inside ► [parasitophorous vacuoles](#)

When they have digested these agents, they present the MHC I or MHC II complex at their surface, so that the B-lymphocytes can become informed (via CD 4 cells) to produce antibodies. However, some parasites (e.g., *Toxoplasma* (Fig. 1), ► [Leishmania](#)) grow inside such cells and destroy them.

Macroponema

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Genus of nematodes (Strongyloidea, Cloacininae) parasitizing in kangaroos, e.g., *M. comani*.

Further Reading

Magnetic Resonance Imaging

Syn. NMR-tomography, non-invasive, computer-directed method to diagnose cysts of *Echinococcus*, *Taenia cysticerci*, *Entamoeba* abscesses or ► [Paragonimus](#) or *Schistosoma* granulomas.

Major Histocompatibility Complex (MHC)

There are two complexes which are presented by macrophages either to T₈ – cells (from cells infected with viruses, MHC 1) or to T₄ – cells (from cells infected with, e.g., parasites, MHC 2). The first cell type excretes perforine, the second informs by excreting interleukine 2 the B-cell system.

Major Sperm Protein

Protein of nematode sperm, that facilitates the crawling motility of these sperms (without flagella). It is a 14.5 kDa polypeptide forming a dynamic cytoskeleton that anchors to the plasma

membrane at the leading edge of the pseudopod and then treadmills rearward to the cell body. The MSP's of *Ascaris* and *Caenorhabditis* form symmetric homodimers in solution that polymerize into helical subfilaments that wind together in pairs to form larger coiled structures. In *Ascaris* the sperm cytoskeleton has about 20–30 branched filament networks or fiber complexes. ► [Nematodes](#).

Mal de Caderas

Disease (paresis) due to infection with *Trypanosoma equinum* that is transmitted to horses and cattle, mechanically by bites of ► [tabanids](#) and ► [vampire bats](#) in South and Central America.

Malachite Green

Product that acts against several fish parasites (e.g., ► [Ichthyophthirius](#)).

Malachowski, Ernst (1857–1934)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Polish-German physician, who added in 1889 perhaps the single most valuable contribution to the blood stain, since until his discovery no one had seen the nucleus of the plasmodium cell (► [Plasmodium](#)). Due to his special modification of the methylene blue component of the stain, he was the first to produce the color of royalty in histochemical staining. During 1888–1890, Malachowski started using the Checinski-Plehn double stain method and ameliorated it by polychroming.

Malaria

Caroline Lin Lin Chua
Department of Medicine (Royal Melbourne Hospital), The University of Melbourne, Parkville, VIC, Australia

Name

Latin: *malus* = bad, *aria* = air.

Pathology

► *Plasmodium* spp. parasitize the red blood cells, which are metabolized during the schizogonic cycle, leaving pigment granules. Reticular and endothelial cells phagocytize red blood cell fragments and accumulate malarial pigment. *P. vivax* and *P. ovale* predominantly infect the relatively scarce young red blood cells, thus restricting the level of parasitemia. *P. falciparum* and *P. malariae* infect mature cells, a few or many of which may be infected, often resulting in anemia. Red blood cells parasitized with *P. falciparum* are sequestered in capillaries of internal organs by ► **knobs** on their surface reacting with receptors on the vascular endothelium, thereby causing tissue anoxia. This is particularly serious in the brain (► **pathology**/Fig. 15), where endothelial cells die and capillaries break, giving rise to multiple petechial hemorrhages. Brain anoxia leads to edema and coma, which may be fatal in a few hours. Occasionally glial reactions are seen in response to microinfarcts.

Hepatic damage leads to deep jaundice. Phagocytosis of destroyed red cells imparts a brownish

and, after fixation, a slate-gray color to the enlarged liver and spleen. However, malarial pigment must be differentiated from formalin pigment or acid hematin. Marked renal tubular necrosis is sometimes seen with hemoglobinuric nephrosis in the presence of anoxia and acidosis, the so-called blackwater fever. Deposition of immunoglobulin in the glomeruli may lead to mesangial thickening. The preerythrocytic cycle of *P. falciparum* takes place in the liver, and large schizonts are occasionally seen in hepatic parenchymal cells. With *P. falciparum*, ► **schizogony** proceeds easily in the maternal sinuses of the placenta leading to fetal anoxia, placental and fetal edema, and ► **abortion** after the third month of pregnancy.

Immune Responses

One of the underlying difficulties still hindering the successful malaria vaccine design at the beginning of the twenty-first century is our incomplete knowledge of the precise type(s) of immune responses involved in the control of the different stages of the parasite on the one hand and malaria immunopathology on the other hand. Understanding the nature of the effector mechanisms to blood-borne plasmodia in humans so far has proven intractable since only blood samples on just one or a few time points have been analyzed, and in most cases, little is known on the detailed parasitological and immune status of the subject studied. The pliability of rodent systems for investigating immunoregulation has provided valuable insight into the balance between protection and pathology in human malaria. However, there are important differences in the antiparasitic responses between humans and rodents. First, immunity in mice to various malaria parasites can develop within weeks following infection, but rapid acquisition of immunity to malaria is not observed in humans. Children in endemic areas can take several years to develop effective immunity, while this occurs much faster in adults. A second obvious difference regarding the course of infection in both species is that parasitemias are typically much greater in mice than in humans,

which might be explained by the fact that rodent plasmodia are not natural parasites for mice.

Nevertheless, various murine models have been developed with parasites isolated from African wild rodents. There are four rodent malaria species (*P. berghei*, *P. chabaudi*, *P. vinckei*, and *P. yoelii*) which allow investigation of diverse aspects of the host immune response to malaria. While *P. berghei* and some *P. vinckei*, *P. chabaudi*, and *P. yoelii* strains are lethal to mice, other strains such as *P. chabaudi adami*, *P. chabaudi chabaudi*, and *P. vinckei petteri* cause infections in mice which resolve after initial parasitemia and are either eliminated completely (*P. yoelii* strains) or have smaller patent recrudescences. Although no single model reflects infections exactly in humans, the different models together provide valuable information on the mechanisms of immunity and immunopathogenesis.

One of the most studied models is that of *P. chabaudi chabaudi*-infected mice most closely resembling *P. falciparum* infection of humans since (1) it usually infects normocytes and (2) undergoes partial [sequestration](#) (although in the liver and not in the brain) and (3), in resistant strains of mice, there are recrudescences by parasites of variant antigenicity.

Protective immunity to the asexual blood stages of malaria parasites, the pathogenic stage of the life cycle, involves both cellular and antibody-mediated mechanisms.

Innate Immunity

GPI anchors have been identified as a major pro-inflammatory agent in *P. falciparum*. GPI anchors, in the 0.1–10 μ M range, isolated from the erythrocytic stage of the *P. falciparum*-derived merozoite surface proteins, were shown to induce IL-1 and TNF- α secretion by murine macrophages. Removal of the fatty acids linked to the glycerol portion by phospholipases abolished most of the cytokine induction, indicating that the lipid moiety plays an essential role in the macrophage activation process. Studies performed in different mouse models suggest the importance of pro-inflammatory cytokines both in resistance to early infection and in pathogenesis. While MyD88-deficient mice displayed a

decreased production of endogenous IL-12 and less severe pathology than the WT mice, no clear phenotype was observed when KO mice with a specific TLR deficiency were infected with a highly virulent strain of *P. berghei*.

B Cells and Antibodies

In both humans and mice, passive transfer of antibodies from immune individuals to those suffering from acute malaria resulted in quick and marked reduction of parasitemia. Most recently, it has been reported that antiadhesion antibodies, which limit the accumulation of parasites in the placenta, appear in women from Africa and Asia who have been pregnant on previous occasions (multigravidas). These antibodies were found to be associated with greatly reduced prevalence and density of infection. In addition, infections with *P. berghei* and *P. yoelii* cannot be controlled in mice from which B cells are removed by neonatal anti- μ treatment, and the elimination of parasites is also impaired in mice with a targeted deletion of the JH-gene segment of the Ig gene locus. While IgG2a is essential in the mouse model, IgG1 and IgG3 appear to be most effective in humans. In addition several epidemiologic studies have shown a strong association of IgG1 and IgG3 antibodies with immunity to *P. falciparum*, and the same antibody subclasses might also account for the resistance of newborns delivered by malaria-immune mothers in malaria-endemic areas.

IgG1 and IgG3 in humans and IgG2a in mice are cytophilic isotypes able to promote activation of monocytes and macrophages via Fc receptors. The antibody-dependent killing of parasites in vitro is either dependent on the presence of mouse neutrophils or human monocytes. One mechanism possibly involved in this antibody activity is the induction of TNF by monocytes leading to growth inhibition of intracellular parasites in neighboring cells. In fact, anti-TNF antibodies prevented asexual parasite growth inhibition, and parasite inhibitory activity is present in cell-free supernatants. Selective agglutination of infected erythrocytes is consistently associated with reduced parasite density. There is growing evidence that both opsonizing and

agglutinating antibodies recognize PfEMP1 (*P. falciparum*-infected erythrocyte membrane protein 1), a group of large (200–350 kDa) proteins inserted into the red ► [cell membrane](#) by mature asexual blood-stage parasite. PfEMP1 proteins play a critical role in the retention of infected erythrocytes in the blood vessels avoiding sequestration of the parasite in the spleen, since PfEMP1 interacts with a variety of endothelial receptors such as CD36, E-selectin, thrombospondin, vascular cell adhesion molecule 1, and intercellular adhesion molecule 1. Thus, an important function of antimalaria antibodies might be the inhibition of endothelial cell–blood cell interaction but facilitating the interaction of opsonized infected erythrocytes with phagocytes in the spleen. Indeed, it has been shown that the spleen is essentially involved in the IgG2a-dependent clearance of *P. berghei* and *P. yoelii* in mice.

T Cells

Two stages of the malaria parasite are truly intracellular, that which infects the liver and the asexual stage which resides in red blood cells. Since intracellular parasitism is a strategy for evading antibody-dependent immune responses, T cells most likely are involved in the defense against malaria. Infections with plasmodia stimulate CD4⁺, as well as CD8⁺ αβ T-cell receptor-expressing T cells, and γδ TCR⁺ T cells. While mice genetically deficient for αβ TCR T cells were very susceptible to *P. chabaudi* infection and died rapidly after infection, there was no difference between γδ TCR-deficient mice and control mice. However, there is a differential expansion of γδ T-cell subset in the peripheral blood and spleens of mice and humans, and it has been shown in the *P. chabaudi adami* mouse model that the γδ T-cell blast response coincides with the remission of parasitemia. Since γδ T cells proliferate in response to malaria antigens, e.g., ► [heat shock proteins](#), in vitro, the systemic expansion of this T-cell subset in vivo might reflect the systemic release of malaria exoantigens liberated from parasitized erythrocytes upon ► [schizont](#) rupture.

CD8⁺ T cells mediate killing of the liver stage of plasmodia, possibly by producing cytokines (IFN-γ, TNF) which induce the production of NO by infected hepatocytes.

The central role of CD4⁺ T cells for the protective immunity against the asexual blood stages of experimental malaria has been shown by in vivo cell depletion analysis and by cell transfer studies. Since transfer of purified CD4⁺ T cells or of CD4⁺ T-cell lines to SCID mice or lethally irradiated mice cleared the infection only in the presence of B cells, there is the need for T-cell–B-cell interaction in the establishment of a fully protective immune response to malaria parasites.

It has been demonstrated that the host-protective response in *P. chabaudi chabaudi*-infected mice involves both Th1-type and Th2-type CD4⁺ T cells. The relative contribution of these subsets changes during the course of infection: While Th1 cells predominate during the acute phase, Th2 cells are primarily found during later phases of infection. However, among the nonlethal murine malarias, *P. chabaudi chabaudi* can be seen in an intermediate position between 2 poles of protective immunity. Whereas a strong Th1 response is involved in the response against *P. chabaudi adami*, a dominant Th2 cell activation is found after infection with *P. yoelii* and *P. berghei*. The severeness and ► [lethality](#) of an infection appears to be linked to the early and strong induction of a Th2 response. This is best demonstrated by the fact that infection with a nonlethal strain of *P. yoelii* leads to both Th1 and Th2 activations, while in the case of an infection with a lethal strain of *P. yoelii*, only a Th2 response was detectable. It is unknown, however, why more severe infections fail to trigger an adequate Th1 response.

A protective function of both Th1 and Th2 cells has been indicated by cell transfer experiments to *P. chabaudi*-infected mice. The protective effect of transferred Th1 cells could be blocked by inhibitors of iNOS (L-NMMA), while in contrast resistance conferred by Th2 cells was not influenced. Even in the case of Th1 cells, there are clearly NO-independent mechanisms of protection involved, since Th1-mediated protection against *P. yoelii* is not

dependent on NO. Protective Th2 cell clones specific for *P. chabaudi chabaudi* drive a strong protective malaria-specific IgG1 response in vivo (see above) which is promoted by IL-4.

An interesting phenomenon observed is the temporal shift from Th1- to Th2-regulated immunity during *P. chabaudi chabaudi* infection of mice. It has been suggested that the type of antigen-presenting cell is critically involved in the Th cell differentiation process. While during the first days of infection professional antigen-presenting cells such as dendritic cells or macrophages might favor the development of Th1 cells, the subsequent activation of malaria-specific B cells appears to be responsible for the observed Th2 cell differentiation. The latter is strongly suggested by the fact that mice rendered B-cell deficient by lifelong treatment with anti-IgM antibodies or by targeted disruption of the Ig- μ -chain gene are unable to generate a malaria-specific Th2 response, while the ability to develop Th1 cells is not altered.

In addition to the type of antigen-presenting cell or the cytokine milieu, the antigen concentration is also involved in the regulation of the different Th subsets. Whereas high-dose challenge of resistant mice led to an enhanced Th1-mediated immune response, low-dose challenge causes more pronounced Th2 cell development.

Given the central protective role of CD4⁺ T cells in murine models of malaria, it is still puzzling that there is no major effect of the HIV pandemic on the incidence or severity of human malaria, as has been observed for tuberculosis, toxoplasmosis, or leishmaniasis. It has been speculated that progression to ► [AIDS](#) involves a preferential depletion of Th1-type CD4⁺ T cells and not Th2-type cells and that the latter might be sufficient to allow a protective antibody-mediated immunity to malaria to be maintained.

The early burst of IFN- γ production by CD4⁺ T cells (Th1) as found in *P. tabai chabaudi*-infected mice appears to be important for the control of primary parasitemia, since neutralization of IFN- γ or injection of rIFN- γ , respectively, exacerbates or inhibits the infection. Part of the protective IFN- γ -mediated effects might be due to the enhancement of TNF production by

macrophages. It has been reported recently that the Th1-associated increase in endogenous TNF in the spleen during early infection correlates with resistance to *P. chabaudi chabaudi*, whereas high TNF levels in the circulation and liver late after infection have a deleterious effect for the host. Because TNF and IFN- γ are not directly toxic for plasmodia, the main effect of these two cytokines contributing to the ► [control of malaria](#) is most likely the enhancement of macrophage cytotoxic activity. Regulatory T cells may have detrimental functions in malaria. In a murine model of malaria, depletion of natural T_{reg} protected mice from death caused by the lethal strain of *P. yoelii* by restoring an efficient effector immune response, which eradicated the parasites. Similarly, in humans infected with *P. falciparum*, removal of T_{reg} in vitro enhances peripheral blood mononuclear cell proliferative and IFN- γ responses to malaria antigen.

Control of Parasites by Activated Macrophages

TNF and IFN- γ together with parasite exoantigens activate macrophages to secrete several products into the local environment among which are reactive oxygen and nitrogen derivatives. Although reactive oxygen derivatives are toxic for plasmodia in vitro, the in vivo studies yielded conflicting results. Injection of the ROI scavenger hydroxylanisole resulted in enhanced parasitemia in *P. chabaudi adami*-infected mice. In contrast, P/J mice with an intrinsic defect for the generation of ROI resolve acute *P. chabaudi chabaudi* infection.

It has been argued that NO might be an improbable defense mechanism against blood-stage malaria since the hemoglobin in intimacy with intraerythrocytic parasite has a high affinity to NO and may thereby scavenge this molecule. Nevertheless, NO and related compounds are able to inhibit the growth of several ► [Plasmodium](#) spp. in vitro at concentrations in the range generated locally by activated macrophages (40–100 μ M). In the presence of hemoglobin, this activity of NO is dependent on the local O₂ tension. While at high O₂ tension the formation of S-nitroso-hemoglobin is favored, at low O₂

tension the S-nitroso-hemoglobin functions as NO donor.

A protective role of NO *in vivo* has been demonstrated by studies with iNOS inhibitors. Injection of L-NMMA during the ascending parasitemia caused elevated parasitemia of extended duration, and as mentioned above, the protective effect of Th1 cell transfer was significantly reduced by L-NMMA treatment. A correlative support for the involvement of NO in the defense against malaria comes from the observation that iNOS expression was inversely proportional to the disease severity in African children with *P. falciparum* infection.

In addition to direct antiparasitic effects of NO, other host-protective functions of this molecule have been proposed: NO is able to inhibit leukocyte adhesion to the endothelium and to increase vasodilation thereby possibly preventing hypoxic tissue damage.

Immunopathology

Besides its protective function, the cellular immune response to malaria is also involved in the pathogenesis of the disease. Already more than 15 years ago, it was reported that CD4⁺ lymphocytes play a major role in the pathogenesis of murine cerebral malaria. The transfer of malaria-specific Th1 cells to SCID mice reduced parasitemia, but the animals died early at low parasitemia, indicating T-cell-mediated immunopathology.

There is evidence that the systemic pathology is due to an exuberant inflammatory response to the parasite resulting in manifestations such as ► [diarrhea](#), nausea, fever, anemia, and cerebral malaria. TNF, produced either by activated macrophages or T cells, appears to be a central molecule in this scenario. In humans, high serum levels of TNF are associated with a poor outcome of cerebral malaria, and homozygosity of the TNF2 allele, causing enhanced TNF transcription by a different TNF promoter, predisposes children to cerebral malaria. This important role of TNF in the pathogenesis of malaria has focused most interest on malaria toxins as TNF inducers. Several molecules, such as ring-infected erythrocyte surface antigen (RESA), the ► [merozoite surface](#)

[proteins](#) MSP1 and MSP2, a soluble protein complex known as AG7 complex, and lipid moieties, have been shown to induce the production of TNF.

Overproduction of IFN- γ is also of relevance to the development of cerebral malaria. In synergy with TNF, IFN- γ stimulates the upregulation of adhesion molecules like ICAM-1 on endothelial cells in the brain, implicated in the pathogenesis of the disease. The critical balance between protective and immunopathologic effects of cytokines like IFN- γ and TNF is tightly controlled by anti-inflammatory cytokines such as IL-10. In line with this, the susceptibility of IL-10-deficient mice to an otherwise nonlethal infection is not simply due to a dominant parasitemia, but is associated with an enhanced IFN- γ production.

Most recently, it has been shown that mice depleted of $\gamma\delta$ T cells by mAb treatment did not develop cerebral malaria after infection with *P. berghei*, suggesting an important function of this T-cell subset in the pathogenesis of at least some manifestations of malaria.

Evasion Mechanisms

Malaria parasites are obviously able to avoid a protective immune response, since people subject to repeated infections in malaria-endemic areas rarely develop complete or sterile immunity to the parasite. Repeats in the structure of parasite surface proteins may help the parasite to evade host immunity by exhibiting sequence polymorphism and preventing the normal affinity and isotype maturation of an immune response. Furthermore, some of these proteins may act as B-cell superantigens and, when expressed in large quantities, capture protective antibodies. Sequence diversity and ► [antigenic variation](#) in nonrepetitive parasite molecules located on the surface of infected erythrocytes, e.g., the existence of five different variable antigen types (VAT) in the case of *P. chabaudi*, have also been described as potential mechanisms of ► [immune evasion](#).

Vaccination

Human malaria is, among animal and human parasite protozoan diseases, the one for which the

most intense effort of research has been accumulated in the last decades in view of the development of vaccines. Scientific literature on this topic accounts for thousands of references every year, particularly concerning *falciparum* malaria. This is comprehensible because of the importance of malaria as a leading cause of ► **morbidity** and mortality in the tropical areas of the world, with an estimated 300–500 million cases each year and more than one million deaths, mainly among children below 5 years of age in Africa.

A naturally ► **acquired immunity** against malaria is observed in endemic areas where people are exposed to frequent infections. This immunity develops slowly and is characterized, in a first step, by the acquisition of clinical resistance to symptoms, clinical immunity, and later by the ability to control parasitemia at a low level, antiparasite immunity, usually fully expressed only in adults. Classical experiments of British immunologists working in Africa showed in the 1960s that the natural immunity was antibody dependent, directed against the asexual blood stages of the parasite. More recently, seroepidemiological surveys in endemic areas have shown the existence of ant sporozoite-specific antibodies as well as antibodies and CTL cells directed against antigens of the hepatic stage. Finally, naturally and artificially raised antibodies against the gametocytes and latter forms of the sexual stage have been described as able to block the development of the parasite in the mosquito. These observations indicate that immunity in malaria is stage specific, and this was indeed proved in laboratory experiments with rodent and primate models. Thus, efforts in the construction of vaccines have been directed toward different target alternatives. The starting point was the impossibility of raising vaccines from parasite materials since no culture systems are available for preerythrocytic stages of the parasites, while culture of blood stages (*P. falciparum*) requires growth in human red cells. These constraints made malaria vaccines one of the first domains of medical sciences in which nascent genetic engineering technology was actively

introduced with the aim of preparing subunit vaccines. In principle the ideal target would be the preerythrocytic-stage antigens (sporozoites and hepatic forms) since an effective vaccine against these stages would block transmission. However, an inconvenience of such a vaccine is that it would need to induce sterile immunity, because a surviving ► **sporozoite** or hepatic schizont would be sufficient to produce erythrocyte ► **invasion** and multiplication of the parasite in the blood. Sterile immunity against blood stage, however, is not naturally observed in humans of endemic areas and is usually not experimentally obtained in animal models. In contrast, nonsterilizing, partially active vaccines against asexual blood stages, would be favorable to avoid the development of high parasitemia and presumably reduce severe malaria outcome responsible for mortality. However, it would poorly interfere at the level of sources of infection in an endemic area and, therefore, in the level of transmission. Anti-sexual-stage vaccines or transmission-blocking vaccines would abolish or reduce transmission but would not protect the vaccinated individual from infection (altruistic vaccine). In conclusion, these considerations point to the interest in developing multigene, multistage vaccination approach like the CDC/NIIMALVAC-1, for which preliminary assays are now in course.

Preerythrocytic-Stage Vaccines (Sporozoite and Hepatic-Stage Vaccines)

After the successful vaccination of human volunteers in the 1970s with irradiated sporozoites, the search of the antigen(s) responsible for protection was started. With the development of the monoclonal antibody technology, it was possible to identify the protein responsible for the circumsporozoite reaction named CS protein. As the (anti-CSP) Fab' monoclonal antibody was able to confer protection in rodent malaria infection by *P. berghei*, ► **CSP** was identified as protective antigen. The corresponding antigen of the primate parasite *P. knowlesi* was the first parasite antigen successfully cloned and sequenced by the Nussenzweig, revealing the surprising presence

of amino acid repeats in tandem in the central region of the molecule, which turned out to represent the immune dominant B epitope, target of the protective antibodies. Very quickly, the corresponding proteins of *P. falciparum* (containing repeats of NANP peptides) and *P. vivax* parasites were cloned and sequenced. Synthetic peptides and recombinant fusion proteins were built containing the repeat tandem units of the corresponding CSPs. Vaccine trials using these molecules were performed in human volunteers in 1986/1987 which produced disappointing results with poor protection. However, efforts for improving the immunogenicity of the CSP protein have been recently developed. At the same time, new important knowledge about the structure and functional interaction of the protein with the mosquito and hepatocytes of the human host has been obtained. The region of the CSP molecule responsible for the interaction with hepatocytes (and consequent penetration of the ► [sporozoite](#)) was identified and depends on the presence of an amino acid sequence containing RGD motif (arginine–glycine–aspartic) with heparan sulfate (a protein polysaccharide conjugate) present in the surface of the hepatocytes. The same sequence RGD is present in a second protein of the sporozoite more recently described by the name of TRAP (► [thrombospondin-related anonymous protein](#)). The name TRAP was given by the presence of RGD sequence that is found in thrombospondin. These sequences (or associations of CSP and TRAP polypeptides) have now been included in new sporozoite vaccines' preparations under study. In other studies, genetic analysis using gene disruption techniques has been performed showing the functional role of CSP and TRAP in sporozoite movement and interaction with the salivary glands of ► [mosquitoes](#) and with hepatocytes. Finally, new adjuvants have been used in association with CSP-derived antigens which considerably increased the immunogenicity of the protein. A series of trials (primate and human volunteers) are now in course of development, and sporozoite vaccines are still important hopes for the future of malaria vaccines, particularly in association with other antigens in multistage, multigene vaccines.

In another line of research related to the role of CTL in the cellular immune response, it was shown in animal models that CSP epitopes were expressed in the infected hepatocyte and present in the cell membrane, representing possible target of specific cytotoxic T cells. In addition to CSP, other liver-stage antigens of *P. falciparum* like LSA-1 and LSA-3 (liver-stage antigens 1 and 3) and antigens expressed both in sporozoites and liver stages (SALSA sporozoite and liver-stage antigen) have been used to vaccinate primates with induction of partial protection against sporozoite challenge.

Asexual Blood-Stage Vaccines

Asexual blood-stage antigens account for the larger number of molecules, essentially polypeptides, described as potential vaccine candidates. Corresponding genes have been isolated and completely and/or partially sequenced. An abundant literature has been accumulated in the past decades about these antigens concerning molecular biology, immunological assays, experimental vaccination of primates, seroepidemiological surveys, etc. This is comprehensible in view of the demonstration by the British immunologists in the 1960s, confirmed and developed by others, on the ability of antibodies from immune adults in Africa to control blood parasites and symptoms of acutely infected patients. In consequence the search for identification of protective antigens of the asexual blood stage followed two strategies: (1) differential recognition by antibodies from sera of immune and acutely infected Africans using immunoprecipitation and western blot techniques and (2) recognition by monoclonal or/and monospecific polyclonal antibodies able to inhibit the parasite in *in vitro* assays. In this entry, we will summarize recent progress concerning the main antigens defined as those that have been used with success in experimental vaccination of primates promoting at least partial protection.

► [Merozoite surface protein 1](#) (MSP1) is the most studied malaria antigen for *falciparum* and *vivax* parasites. The original protein of 185–200 kDa undergoes a double processing at the ► [merozoite](#) surface: In a first step, three products of 83 kDa (N-terminal), 36 kDa, and

C-terminal 41 kDa originate; in a second step, the 41 kDa fragment is proteolytically cleaved in a 33 kDa and a 19 kDa products. The C-terminal 19 kDa polypeptide is cysteine rich, contains two epidermal growth factor domains, and is the only part of the MSP-1 molecule that penetrates the red blood cell with the merozoite. Numerous vaccination experiments have been performed in primates using the whole molecule or recombinant corresponding to the 83, 41, and 19 kDa fragments or synthetic peptides corresponding to sequences of the N- or C-terminal regions. The better protection in monkey trials has been obtained with the whole natural molecule, but positive results have also been regularly referred with the subunit molecules for *falciparum* and *vivax* malaria, as well as in rodent models using the equivalent molecules. Both antibodies (inhibiting red blood cell invasion) and cellular immune responses have been described in the protective mechanisms.

MSP-3 antigen and GLURP (glutamate-rich antigen) were described as involved in an antibody-dependent cellular inhibition (ADCI) in vitro assay that correlates with natural immunity and has induced partial protection effect in primate vaccination experiments.

Other merozoite antigens that have shown protective effect in monkey trial areas are RAP1/2 (rhoptry antigen), AMA-1 (apical membrane antigen), and EBA-175 (erythrocyte-binding protein of 175 kDa) which are discharged on the red blood cell by the merozoite during the invasive process. It might also be referred to as the ► [SPf66](#) of Patarroyo et al., a polymerized chimera peptide containing sequences of the MSP-1 N-terminal region, two unknown antigens, and the sporozoite NANP sequence. SPf66 has been extensively used in monkey and human trials, but final evaluations indicate a disappointing poor or absent protective effect.

A second family of asexual blood antigens is represented by proteins secreted by the parasite in the plasma, i.e., ► [PfHRP-2](#) (histidine-rich protein 2), Ag2, and ► [SERA](#) (serine-rich protein). SERA antigen, also described as Pf140 and Pf126 codes for a protease of unknown function, is localized in chromosome 2 where no less than

eight copies of closely homologous sequences are present in tandem. Very good protection was obtained in monkey trials using recombinant proteins of the original SERA.

Finally, parasite antigens associated to the red cell membranes have been shown to represent targets of opsonizing antibodies that can mediate ► [ADCC](#) or phagocytosis by macrophages. The Pf332 and ► [PfHRP-2](#), in this family, have been described as inducing partial protection in primate trials. The PfEMP-1 (erythrocyte membrane protein) has now been identified as the antigen derived from the polygenic family of the variant antigen *var* gene family with 50–100 copies showing extensive polymorphism. Some of the variant antigens could be associated to severe malaria by promoting sequestration of schizonts in capillary venules of the brain and other tissues. Intensive search for common structures of *var* genes products, to be used as vaccine targets against cerebral malaria, is now in progress in many laboratories. This goal was recently complicated with the description of other families of variant antigens, under the names of ► [stevor](#) and ► [rif](#) that seem exposed at the infected erythrocyte membrane.

In the slow development of immunity in high endemic areas of *falciparum* malaria, the first step, already observed in children over 5–7 years, is the reduction in disease severity which evolves to complete asymptomatic infections, eventually with high parasitemias. The similarity between the malaria attack and the toxemic shock produced by bacterial LPS induced the search of malaria toxins which became a preferential area of research. Such toxins would be released at the schizont rupture and be responsible for the secretion of TNF- α by immunocompetent cells. TNF- α is found at very high levels in the blood of severe malaria patients and has been shown to correlate with the severity of the illness. The contamination with *Mycoplasma* of *Plasmodium* lines maintained in vitro raised numerous questions about potential artifactual nature of some of the work describing the so-called malaria toxin published over the last 10 years. Among the many parasites – derived molecules proposed to fulfill the function of a toxin in terms of TNF- α

production – the ► **GPI anchor** of membrane proteins of the merozoite remains the only still accepted candidate. Other molecules such as phosphorylated nonpeptidic antigens (termed as phosphoantigens) are also molecules inducing TNF- α production by $\gamma\delta$ T cells, which could contribute to physiopathology of the illness. None of these potential toxins have yet been prepared in conditions allowing use in vaccination trials.

Sexual-Stage Vaccines (Transmission-Blocking Vaccines)

The description of parasite antigens specific of the latter stages of the sexual development of the parasite provides interesting candidates for an altruistic vaccine. Natural antibodies from infected humans and raised monoclonal antibodies have shown, indeed, their ability to block parasite development in the mosquito. These antigens which are not seen by the immune system of infected humans have thus inspired the search for candidates for transmission-blocking vaccines. The rationale of such altruistic vaccine is that immunized people would produce antibodies able to inhibit the parasite development in the mosquito and thus interfere with the natural life cycle of the parasite. Among the various candidate antigens, the most promising is the Pfs25 (and equivalent in *P. vivax*) for which phase I and IIa trials have been completed.

Planning of Control

Attempts to control malaria date back to ancient times, but a rational fight against the disease only became possible after the discovery of the parasite's life cycle, early in the twentieth century. Control then consisted of measures against the anopheline vectors, mainly in their larval forms, and the use of quinine for treatment. Conditions improved with the introduction of potent residual insecticides and highly effective drugs in the late 1940s. At that time three-quarters of the world's population were living in malarious areas. The new tools were considered effective enough for attempting malaria eradication in

wide areas of the globe, with the exception of tropical Africa. Malaria eradication was achieved in more than 30 countries, freeing more than one-third of the formerly affected areas from the disease. In other countries, the goal of eradication was not attained, but the disease's impact was greatly reduced. Since the late 1960s, there has been a stagnation and, in some areas, a deterioration, of the malaria situation, and the problem of the disease's hard core in tropical Africa is still unresolved.

Today malaria is still endemic in 100 countries and approximately 40 % of the world's population lives in malarious areas. The annual number of clinically manifest cases is estimated at 300–500 million and the annual number of deaths due to malaria at 1.5–2.7 million. There is a large reservoir of chronically infected persons, especially in Africa. Approximately 90 % of malaria cases occur in tropical Africa, nearly 10 % in Asia and Western Oceania, and less than 1 % in the Americas. *P. falciparum*, the most dangerous and most widely distributed species of malaria parasites, accounts for approximately 90 % of all infections worldwide. It is the lead species in tropical Africa, where it is often accompanied by *P. malariae*. In subtropical areas outside Africa, *P. vivax* prevails over *P. falciparum*. The occurrence of *P. ovale* is practically restricted to tropical Africa.

In a policy statement on the implementation of the global malaria control strategy, the World Health Organization stated that the goal of malaria control is to prevent mortality and reduce morbidity and social and economic loss, through the progressive improvement and strengthening of local and national capabilities. The four basic technical elements of the global strategy are:

- To provide early diagnosis and prompt treatment
- To plan and implement selective and sustainable preventive measures, including ► **vector control**
- To detect early, contain, or prevent epidemics
- To strengthen local capacities in basic and applied research to permit and promote the regular assessment of a country's malaria

Malaria, Fig. 1 Targets and approaches for the control of *Plasmodium falciparum* malaria

situation, in particular the ecological, social, and economic determinants of the disease

In view of the vastly different resources available for malaria control in various countries and of the substantial differences in the intensity of malaria transmission and the capability of conducting health program, it will be useful to differentiate the following levels of achievement as objectives of antimalaria action:

1. Elimination of mortality and reduction of suffering from malaria
2. Reduction of the prevalence of malaria
3. Elimination of malaria

Level 1 can be achieved by the timely detection and effective treatment of malaria cases and the protection of specific vulnerable groups. This requires the wide availability of health-care facilities throughout the malarious areas and a well-developed, rapid, and efficient referral system that can cope with severe and complicated malaria. Primary health care, backed up by efficient secondary and tertiary health-care structure, is the vehicle through which this most elementary objective can be reached. Wherever they were

established, malaria clinics proved to be a very useful component of the system. The reliance on drugs as the primary tool necessitates continuous monitoring of drug response and adherence to strict policies for rational drug use. A major constraint is the lack of sufficiently simple and cheap diagnostic techniques which do not require oil-immersion microscopy. In areas with intensive malaria transmission, it has been shown that the detrimental impact of malaria (mortality and clinical incidence) can be substantially reduced by the use of pyrethroid-impregnated bed nets.

Level 2 requires measures directed against the transmission of malaria in addition to those needed for achieving level 1. This will be more demanding in terms of resources and skills. Based on sound epidemiological knowledge, proper operational stratification, and the results of feasibility studies, the appropriate approaches are to be selected for each operational area in accordance with the degree of control that is to be achieved. Here the focal application of vector control measures may be required and therapeutic intervention based on the microscopic diagnosis of malaria. Level 2 is therefore more demanding in technical skills and guidance, and specialized manpower may also be required in the periphery.

M

Continuous evaluation is indispensable in order to detect changes in the response to certain measures and to adapt operational procedures accordingly.

Level 3 is still realistic for some countries and may come into the reach of others if and when more effective antimalaria tools become available. Under this objective, malaria is regarded as a parasitosis rather than a disease. This implies that every malaria infection, whether symptomatic or not, is of importance and requires radical treatment in order to eliminate infective reservoir. The traditional malaria eradication campaigns relied on a very limited choice of attack measures and on a vertical service structure. This will not be appropriate in the future since the selection of operational approaches will require more flexibility and the fast flow and utilization of epidemiological information. Level 3 should be

understood as a logical extension of level 2. See also ► [Disease Control, Epidemiological Analysis](#) (Wernsdorfer, Vienna).

Targets for Intervention

Targets of intervention (Fig. 1) are infected humans, the vector, and the infection cycle. Approaches are numerous and their selection depends on the given epidemiological situation, the available resources, and the envisaged level of control. Treatment of infected persons may be suppressive or radical and gametocytocidal. Vector control may be directed against the aquatic stages of ► [Anopheles](#), the adult mosquitoes, or both. The interruption or reduction of man–vector contact is a valuable ancillary measure.

Malaria, Fig. 6 LM of a Giemsa-stained gamont of *Plasmodium falciparum*, which are typically banana shaped in human blood (From Jensen and Mehlhorn 2009)

Main Clinical Symptoms

- (a) *Plasmodium vivax* (malaria tertiana): Fever of 40–41 °C for several hours (after 1 h of shivers) is repeated within 48 h (Fig. 4 e-h).
- (b) *P. ovale* (M. tertiana): As in *P. vivax* infections (Fig. 4 m-p).
- (c) *P. malariae* (M. quartana): Rhythmic fevers of 40–41 °C (after shivers) reappear within 72 h (Fig. 4 i-l).
- (d) *P. falciparum* (malaria tropica): Irregular high fevers of 39–41 °C appear continuously after a phase of headache and general abdominal symptoms; fevers may be rhythmic (48 h) or even absent (Fig. 4 a-d); eventually followed by coma and death.

Incubation Period

- (a) *P. vivax*: 12–18 days, occasionally longer
- (b) *P. ovale*: 10–17 days
- (c) *P. malariae*: 18–42 days
- (d) *P. falciparum*: 8–24 days

Prepatent Period

- (a) *P. vivax*: 8–17 days, occasionally longer
- (b) *P. ovale*: 8–17 days
- (c) *P. malariae*: 13–37 days
- (d) *P. falciparum*: 5–12 days

Patent Period

- (a) *P. vivax*: up to 5 years
- (b) *P. ovale*: up to 7 years
- (c) *P. malariae*: 30 years and more
- (d) *P. falciparum*: under treatment 4–6 weeks, without treatment 18 months

Diagnosis: Microscopic determination of stages in blood smears and thick droplets (Figs. 4 a-p); malaria quick tests in *P. falciparum* commercially available.

Prophylaxis: Avoid the bite of *Anopheles* mosquitoes (see ► [Repellents](#), Insecticides), and use ► [chemoprophylaxis](#) in endemic regions.

Therapy: For treatment, see ► [Malariacidal Drugs](#).

Malaria and Pregnancy

Caroline Lin Lin Chua
Department of Medicine (Royal Melbourne Hospital), The University of Melbourne, Parkville, VIC, Australia

Malaria in pregnancy poses a serious threat to many pregnancies around the world, particularly in areas of intense malaria transmission and poor availability of health resources. Every year, approximately 125 million pregnancies occur in malaria-infected countries (Dellicour et al. 2010), with an estimated 10,000 maternal and 100,000 infant deaths attributed to malaria in pregnancy (Guyatt and Snow 2004). Maternal deaths were mainly due to severe malarial anemia, whereas infant deaths were associated with their low birth weight, defined as weighing less than 2500 g at the time of birth.

Malaria parasites can circulate from maternal peripheral blood to the placenta. Pregnant women with malaria-infected placenta are more likely to deliver low birth weight babies, with approximately 130 g reduction in birth weight (Allen et al. 1998). In the presence of heavy inflammation, known as massive chronic intervillitis, this risk was elevated fourfold, and birth weight can be reduced up to 500 g (Menendez et al. 2000).

There are two main ways by which malaria can lead to low birth weight: by induction of premature delivery, where the duration allowed for fetal growth has been significantly shortened, and by intrauterine growth restriction, where the fetus is born at term but may have been prevented from reaching its full genetic growth potential through disruption to in utero growth. The latter is the predominant pathogenetic mechanism underlying low birth weight in malaria-endemic areas. A few mechanisms leading to malaria-associated low birth weight have been proposed, including impairment in nutrient transport, dysregulated angiogenesis, and decreased growth hormone production.

Malaria Containment

Attempts to eliminate outbreaks.

Malaria Eradication Research Agenda

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

See ► [VIMT](#).

Novyella

Synonymous subgenus name for ► *Plasmodium* of a genus of blood parasites of birds (Passeriformes), e.g., *N. homopolare*, *N. ashfordi*.

Further Reading

Walter EL et al (2014) Description, molecular characterization, and patterns of distribution of a widespread New World avian malaria parasite, *Plasmodium* (*Novyella*) *homopolare*. Sp. Nov. Parasitol Res 113:3319–3332

Malaria in Pregnancy

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Pregnant women have a considerably increased risk of *Plasmodium* infections so they in their first pregnancy are (as well as children below 5 years) the primary victims of malaria deaths.

Further Reading

Ataide R et al (2014) Malaria, primigravidae, and antibodies: knowledge gained and future perspectives. Trends Parasitol 30:85–94

Malaria Mosquito Manipulation

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

The finding that ► *Plasmodium* infected mosquitoes interrupt their blood meals more often than noninfected individuals is interpreted by some

authors as active manipulation by the parasites, since repeated short blood meals at different hosts propagate the parasites to a broader spectrum of hosts, which increases the survival rates of a vector-bound parasite.

Cator LJ et al (2012) Do malaria parasites manipulate mosquitoes? Trends Parasitol 28:466–470

Malaria Placental Events

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

During *Plasmodium falciparum* infections of pregnant woman, numerous erythrocytes bearing developmental stages may become accumulated in the villous space of the placenta and thus may introduce considerable inflammations. This may lead, in addition to other reasons, to ► *Malaria*-derived placental insufficiency.

Malaria Prophylaxis

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

These recommendations for chemoprophylaxis are based on the yearly publications of the

German Society of Tropical Medicine and of the WHO. In any case, an additional exposition prophylaxis is strongly recommended by use of mosquito ► [repellents](#).

1. **Region: Mexico to Panama:**
 - No chemoprophylaxis recommended
 - Treatment: chloroquine (= Resochin[®])
2. **Region: Dominican Republic plus whole North and Central South America (except the three states of Guyana/Surinam):**
 - No chemoprophylaxis recommended
 - Treatment: Atovaquone/Proguanil (= Malarone[®]) or artemether/lumefantrine (Riamet[®])
3. **Region: Surinam, two Guyanas:**
 - Chemoprophylaxis: Mefloquin (= Lariam[®]) or atovaquone/proguanil (= Malarone[®]) or doxycycline
4. **Region: Sub-Saharan Africa (with exceptions see below 5, 6):**
 - Chemoprophylaxis: Mefloquine (= Lariam[®]) or atovaquone/proguanil (= Malarone[®]) or doxycycline
5. **Region: Namibia/Northern South Africa:**
 - Chemoprophylaxis: in mosquito season: mefloquine (= Lariam[®]) or atovaquone/proguanil (= Malarone[®]) or doxycycline
6. **Region: Yemen, coast of Tanzania, Sansibar:**
 - No chemoprophylaxis
 - Treatment: Atovaquone/Proguanil (= Malarone[®]) or artemether/lumefantrine (Riamet[®])
7. **Region: India, Pakistan, Thailand, Korea, South-China, Malaysia, Indonesia (pro parte):**
 - No chemoprophylaxis recommended
 - Chemotherapy: Atovaquone/proguanil (= Malarone[®]) or artemether/lumefantrine (= Riamet[®])
8. **Region: Some Indonesian islands (like Lombok), Papua Guinea, Salomones:**
 - Chemoprophylaxis: Mefloquine (= Lariam[®]) or atovaquone/proguanil (= Malarone[®])
9. **Region: Vanuatu**
 - Like region 7

Malaria Relapse

Miles B. Markus

School of AP & ES; and Wits Research Institute for Malaria, University of the Witwatersrand, Johannesburg, Gauteng, South Africa

General Information

It is conventionally assumed that malarial relapse is caused by hypnozoites, via schizogony in hepatocytes. In regard to malaria (as opposed to other diseases), the word “relapse” is nowadays used to refer specifically to renewed parasitemia and illness that originates from presumed hypnozoites in the liver.

A valid alternative term for “hypnozoite” is “dormozoite”. However, it is the former word that has become ubiquitous in the literature; and consequently, use of the name “hypnozoite” is preferable.

The apicomplexan hypnozoite was discovered by Mehlhorn and Markus (1976), when electron microscopy revealed the sporozoite-like nature of a known and apparently dormant extraintestinal stage of *Cystoisospora* (synonym: *Isospora*), an organism closely related to *Plasmodium*. It was a few years later that plasmodial hypnozoites were recognized for the first time, in the laboratory of W. A. Krotoski in New Orleans, USA. These were hypnozoites of the relapsing simian parasite *Plasmodium cynomolgi*. Since then, it has become dogma that hypnozoites are responsible for those *Plasmodium vivax* and *Plasmodium ovale* human malarial recurrences that are not recrudescences arising from parasites in the bloodstream or reinfections resulting from transmission by mosquitoes. However, the existence of hypnozoites of *P. ovale* has been regarded as uncertain and requires well documented, experimental parasitological confirmation. It is possible that not only *P. ovale* recurrences but also those of *P. falciparum* and *P. malariae* are occasionally hypnozoite-mediated (Richter et al. 2016).

Origin of Relapse

There is no in vivo parasitological proof that activation of hypnozoites is responsible for presumed relapses of *P. vivax* infection, despite the fact that this has for the past three and a half decades been stated in textbooks and elsewhere to be the basis of these recurrences. It is a perfectly logical conclusion though, because those *P. vivax* recurrences that appear to be relapses characteristically follow sporozoite-induced infections; and hypnozoites seem to be dormant sporozoites, albeit slightly different morphologically. Recently, nonbloodstream and nonhepatic merozoites that are perhaps quiescent were detected in the life cycles of some rodent *Plasmodium* species, which means that such merozoites might well also occur in the life cycles of malarial parasites of primates. There is indirect evidence for this possibility (if not probability), judging by various instances of long latency (some of which might be associated with other parasite stages, however) in *P. falciparum*, *P. malariae*, and *P. ovale* infections (Markus 2015; Richter et al. 2016). These merozoite forms have been found in the lymphatic system of rodents. Latent merozoites could equally, therefore, be assumed to be the source of benign tertian malarial recurrences, including blood-stage merozoites that may have become temporarily quiescent as a result of drug prophylaxis or treatment (Markus 2015). Excluding the possible drug-associated origin of recurrences, it is far more likely, however, that some *P. vivax* recurrences are the result of hypnozoite activation (i.e., are true relapses), whereas other recurrences (characterized by homologous bloodstream parasites, the source of which is on genetic grounds conceptually not easily ascribable to hypnozoites) have dormant nonhypnozoite stages as their source (Markus 2015). This dual possibility is now becoming recognized (Richter et al. 2016). Initially persisting parasites in the skin or associated draining lymphatic system could theoretically (in the light of other new findings concerning the life cycle of *Plasmodium*) likewise sometimes be responsible, especially for early recurrences.

Cause of Recurrence/Relapse

At the cellular level, what actually precipitates activation (in the case of *P. vivax* hypnozoites and perhaps skin-stage sporozoites) or reactivation (in the case of putative latent *P. vivax* merozoites in the body, i.e., forms that are postdivisional and thus have previously been metabolically active) is not yet known. This is a subject of ongoing speculation and, lately, investigation. Extrapolation to *P. vivax* infection in man might become feasible in due course, following the use of humanized mouse models which are being developed and/or experimentation with *P. cynomolgi* that has started (Markus 2016).

Extended Incubation Periods

Related to and inseparable from the concept of relapse is the idea that hypnozoites are responsible for delayed prepatent and incubation periods (6–9 months) in *P. vivax* malaria, this being the longstanding, traditional view as regards parasitological causation. Whether the quiescent parasites responsible for extended incubation periods are hypnozoites, skin-stage forms, dormant merozoites in the blood or elsewhere internally, or more than one of these possibilities is, in fact, unknown (Markus 2015).

Not only is it the theory of the hypnozoite origin of malarial relapse that is being revisited (Markus 2015) but also this phenomenon of initial long latency, including the (directly relevant) relationship between sporozoite dose and the length of the incubation period in benign tertian malaria. During the last century, a number of sporozoite-associated human studies were carried out. It was reported that inoculation of relatively few sporozoites resulted in longer *P. vivax* incubation periods and fewer recurrences. Conversely, the incubation period has been said to be shorter when larger sporozoite inocula were used, a conclusion that has up until now been accepted by malariologists as being correct. However, recent statistical consideration of results in historical studies, which were limited at the time by available analytic methods, strongly suggests that sporozoite dose is not a primary driver of incubation

periods in experimental and naturally acquired human *P. vivax* infections (Lover and Coker 2014). The true causes have yet to be ascertained. Parasite strain, amongst other factors, is likely to be important.

It is thought that differences in the length of incubation periods might be correlated with the breeding times of vector mosquitoes in the respective areas concerned.

Clinical Relevance

Renewed clinical activity (which contemporary authors usually call “relapse”) can take place weeks, months, or more than a year after the primary *P. vivax* attack in someone who did not get treated, or who received inadequate drug therapy, or in whom treatment was unsuccessful. This aside, Richter et al. (2016) suggested that it might not be necessary for the anti-relapse drug primaquine to be routinely administered for *P. ovale* malaria, and they have provided the associated rationale.

Findings concerning some old strains of *P. vivax* are of informative value in modern malariaology. Illness caused by the tropical Chesson strain would occur several times at frequent intervals, starting soon after an early primary attack. The North Indian, Madagascan, and St Elizabeth strains gave rise to a few recurrences, with the first often taking place many months after an early bout of symptomatic disease which, however, did not always occur.

In general, the frequency of febrile *P. vivax* episodes in tropical areas is usually seen at intervals of approximately 3–4 weeks. A patient may experience a number of such recurrences. In temperate regions, on the other hand, the duration of the asymptomatic period typically tends to be 8–10 months or longer following the first episode of clinical *P. vivax* malaria. Then some recurrences start taking place at short intervals. Whether these intervals are about 3–4 weeks or approximately 6–8 weeks depends on the drug treatment given.

Long incubation periods can be a normal feature of infections with certain *P. vivax* strains, some being of historical importance malariologically. The strain designated as *P. vivax hibernans* was known for not giving rise to an early primary attack. Today, cases of *P. vivax* malaria in the same overall region can be mixed in terms of short and long incubation periods, for instance in Korea, where the proportion of cases with long incubation periods is significantly correlated with meteorological conditions and latitude.

As for the relationship between sporozoite dose and the incubation period, acquisition of understanding in regard to factors involved in determining short and delayed incubation periods is important for planning human *P. vivax* vaccine studies. One possibility is that there might be a dose threshold for dose response to sporozoite inoculation into humans (Lover and Coker 2014).

Malaria Vectors

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und
Parasitologie, Heinrich-Heine-Universität,
Düsseldorf, Germany

The females of approximately 70 out of 400 species of the genus ► *Anopheles* (Greek *anophelos* = harmful, useless), 5–8 mm in size, serve as **vectors** of the malaria parasites. These so-called fever mosquitoes, who prefer regions with high humidity and who splay their abdomens at an angle of roughly 40° from a surface in normal position (Figs. 1, 2, and 3), require the nutrients in the blood of vertebrates in order for

their eggs to reach maturation. The males of this genus feed on the sap of plants and are therefore not potential vectors. **Eggs**, which are able to float using small lateral air chambers, are laid **individually** at night in batches of 70–100 on the surface

Malaria Vectors, Fig. 1 Light micrograph of a female *Anopheles stephensi* sucking at a sugar solution

Malaria Vectors, Fig. 2 Scanning electron micrograph of a female *Anopheles stephensi*

of placid waters. The **larvae** hatch out of these and come to the surface of the water for air. Once there (unlike the *Aedes* and *Culex* genera), the larvae lie flat with their abdomens parallel to the surface of the water (Fig. 3). The larvae feed by filtering organic matter. In 1–3 weeks (depending on temperature) and after 3 molts (=4 larval stages), the larvae reach the **pupal stage**, during which the pupas are still mobile and come to the surface of the water for air, but no longer feed. The pupal period lasts approximately 3–5 days and ends with the hatching of a sexually dimorphic male (antenna with many bristles) or a female (antenna with few bristles) (Fig. 4), such that each successive generation takes about 1.5–3.5 weeks up to 50 days. A female will lay approximately 1,000–3,000 eggs in ten clutches during her lifetime. As a result, enormous numbers of potential vectors come into being, especially in tropical regions where the humidity and temperatures provide ideal conditions for year-round development. If there are not enough “blood donors” near the breeding waters, then the mosquitoes (sometimes swarms of them) are able to travel many kilometers (e.g., they can **proliferate** along coastal zones – with hotels!). Most *Anopheles* species are nocturnal, whereby the females bite in the late evening and early morning. Using their

Malaria Vectors, Fig. 3 Diagrammatic representation of the life cycle stages of species of the genera *Anopheles*, *Aedes*, and *Culex*

olfactory organs, they are able to locate their warm-blooded hosts even in darkness. As **vessel feeders**, they stick their fine, stylet-shaped mandibles directly into blood vessels in the skin. In order to keep the blood from coagulating, they inject an **anticoagulant** with their saliva, which can cause **allergic reactions** of its own around the site of the bite (bumps, itching). Mosquitoes are also definitely able to bite through clothing and the gauze of mosquito netting because their mandibles can grow up to 3 mm long. It takes about 2–4 days for the eggs to develop, making it necessary to feed at this same pace. Since females

obtain blood at least ten times from warm-blooded animals (including humans) during sexual maturity, there is a good chance that they will ingest malaria parasites and transmit them within endemic regions. Their flight radius of 2–3 km/day also brings them easily into the vicinity of potential hosts. Thus, the biology of the *Anopheles* mosquito ensures a high **potential for infection** for blood parasites, such as malaria parasites, even though – unlike with other types of parasites – the malaria parasite is **never** transmitted to the offspring **via the egg**. As a result, protection against mosquitoes (applying repellent

Malaria Vectors, Fig. 4 Diagrammatic representation of the antennae of male and female specimens of mosquitoes; *AF* antenna, *FA* compound eye, *MT* maxillary palps, *R* labium = sucker containing the food and the salivary

channels. Note that the males have numerous bristles at their antennae, which are covered by sensory organs that help to find females

onto the skin and using mosquito nets, etc.) cannot be overemphasized. While **mosquito control** is possible by chemical as well as biological means, a complete eradication of these highly reproductive mosquitoes is likely to remain unattainable (► *Bacillus thuringensis*).

Malaria: Coinfections

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Malaria and non-typhoid *Salmonella* infections occur at a prominent level in sub-Saharan Africa

and cause severe and often fatal illness especially in children. Recent studies have shown that iron deficiency is the important link between both diseases, since increased iron in macrophages supports survival of *Salmonella* spp. inside and thus leads to propagation of this disease. Thus, it has to be feared that iron supplementation programs in these regions (helping suppression of malaria effects) will help to spread non-typhoid *Salmonella* infections.

Malaria: Differential Blood Counts

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

During the last years, blood counts came in the scope of prognostics for infectious diseases such as malaria. The ratio of neutrophil-to-lymphocyte count (NLCR) was proposed as prognostic factor for clinical outcome of malaria and as parameter of systemic inflammation and stress. It was shown that NLCR correlated with parasitemia. Lymphocytopenia and high NLCR are considered as significant predictors of sepsis. Thrombocytopenia and anemia are typical characteristics during and following an infection with *Plasmodium* stages, while leucocytes turned out to be rather stable during such an infection. In addition NLCR and lymphocytopenia were shown to be significant markers for treatment outcome of severe malaria.

Malaria: History of a Worldwide Epidemic

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

History and Significance

Plagues have threatened humans since their early days – nowadays with increasing importance

Malaria: History of a Worldwide Epidemic, Fig. 1 Sculpture of an Assyrian fever devil (~2500 B.C.)

(Hacker 2003; Grüntzig and Mehlhorn 2010, Figs. 1, 2, and 3). **Malaria**, which comes from the *Italian/Latin* (mala aria = bad air), is still the most significant tropical disease to this day. Approximately one million children (especially children <5 years of age) die of this epidemic each year out of an annual total of some 247 million deaths worldwide (WHO 2008). That translates to at least 2,000–3,000 victims every day, whose fate is barely acknowledged in the press, while even the tiniest local misfortune receives widespread public attention through the media. Even though malaria only affects humans and thus there seemed to be a good chance of eradicating it, its status as a major killer has remained largely unchanged. This is due to various factors. While the World Health Organization (WHO) has made tremendous efforts to eradicate malaria since the Second World War, spending many billions of euros, this disease continues to exist in 109 countries (WHO 2008). This is mainly due to

the fact that the vector mosquitoes in these mostly tropical and economically underdeveloped countries are active throughout the year, while at the same time any attempts at proactively and comprehensively controlling the epidemic have proven to be a disaster. As a result, lots of mosquitoes combined with lots of infected people present a situation in these countries, in which the mosquitoes end up passing along the single-cell pathogen to other mosquitoes. The links between the transmission of malaria and the symptoms of the disease were first discovered in the period of 1880–1898, especially through the research of Alphonse ► [Laveran](#) (1845–1922), Ronald ► [Ross](#) (1857–1932), Patrick ► [Manson](#) (1844–1922), and Giovanni Battista Grassi (1854–1925), although the disease has likely accompanied the evolution of humanity since the Middle Pleistocene (780,000–120,000 years ago) (Garnham 1966; Mattingly 1976). There are specific reports concerning tertian fever from the ancient Assyrians and Babylonians (circa 2700 B.C. and 2000 B.C., respectively). Even the Greek physician Hippocrates (460–377 B.C.) was already making a distinction between the 3-day fever and the 4-day fever. An early connection was made between this fever and swamps. The Greek philosopher Empedocles (483–423 B.C.) was successful in combating malaria when he had two small rivers near the village of Selinunte redirected through a swampy area, thus reducing the breeding grounds for mosquitoes. This knowledge was passed on to the Romans, such as Plinius (23–79 A.D.), who was skeptical of ever finding any type of medicinal treatment for the disease, but who considered pepper to be effective. Malaria, which does not discriminate based on social standing, has carried off many nameless millions but also many famous people as well, such as Alexander the Great, German emperors and chancellors (e.g., the Archbishop of Cologne, Rainald von Dassel [1120–1167] – during the siege of Rome by Kaiser Frederick I), famous military commanders, and scientists, thus changing the course of human history at many points in time. As a result, malaria is by all means a social epidemic, which does not spare even the rich and powerful. In order to give an idea of the dimension

Malaria: History of a Worldwide Epidemic,

Fig. 2 The four apocalyptic riders painted by Albrecht Dürer (1471–1526) are said in the bible to come at the end of time and kill mankind by plagues

of the economic impact of malaria, the WHO pointed out in the introduction to World Health Day 2003: “Africa’s gross domestic product today would be roughly 100 billion dollars higher if malaria had been successfully eradicated 30 years ago” (WHO 2003).

Geographic Prevalence

The prevalence of malaria, which is caused by four different single-cell parasites in humans (see below), is linked to certain **factors**, which

are only to be found in a few regions of the world: **water** and **heat**. Water (of a certain degree of purity) is necessary because it forms the habitat for the development of the vector mosquitoes. Fresh water is the preferred habitat, but several species of mosquito have adapted to brackish water (spray zone water). In addition, constant heat is also necessary because the parasites will not reach maturity and become infectious within the “cold-blooded” vector mosquitoes unless the outside temperature remains above 16–18 °C for several days. Based on these reasons, malaria is mostly limited nowadays to tropical and

subtropical zones. This was not always the case. After the Second World War, malaria also occurred within swampy areas or in humid lowlands in relatively temperate zones (e.g., in

northern Italy or even in southwestern Germany and North Rhine-Westphalia, along the Ruhr river). However, the pathogenic foci within these regions have now disappeared because any infected persons received rapid medical treatment and the swamp areas themselves have been drained; while suitable mosquito species are still present – their numbers are low. As a result, people within temperate zones are only at **risk for infection** if they travel to affected regions; however, these regions are often dream destinations for many tourists, due to the beauty of their natural surroundings. These tourists are then especially at risk due to a lack of “semi-immunity,” which the local populations have acquired, as well as a lack of **awareness of the problem** (it is in the economic interest of the tourism industry to make light of the risk). Usually, however, people do not fall ill or experience serious symptoms until they have returned to their home countries. Due to a lack of experience on the part of the local healthcare professionals in dealing with this human parasitosis, misdiagnosis-related complications may occur; these can have life-threatening consequences often resulting in death, especially in the case of malaria tropica parasites (*Plasmodium falciparum*, see below), as evidenced by the 10–15 fatalities each year in Germany *Plasmodium falciparum* (Fig. 4).

Malaria: History of Combating the Disease

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

History of Malaria Treatment from the European Perspective

Since the dawn of human history, it is likely that attempts have been made to treat malaria with herbs and other natural remedies because malaria parasites were present in the Rift Valley, the cradle of humanity, from the very beginning.

The oldest known record of a specific malaria treatment using herbal extracts comes from China in the year AD 340. In the *Handbook of Prescriptions for Emergency Treatments*, **Ge Hong** describes a tea made from a “**handful of mugwort herb**,” which is effective in reducing fever (Klayman 1985). The fever-reducing effect of mugwort herb (genus *Artemisia*) is based on the plasmodicidal properties of the ingredient **artemisinin** which is synthetically produced today and to which almost no resistances exist to date (Noedl et al. 2008). However, just

recently (June 2009) a retarded activity of artemisinin in Cambodia was announced even by BBC London after being shown already by Noedl et al. (2008). In Europe, the healthful effect of mugwort was unknown up until the twentieth century even though the need for malaria medications was high because of the presence of malaria in nearly every European country. Nowadays, however, European malaria and its history have mostly faded into obscurity.

Originally, nearly all the countries north of the Alps and all the way to Scandinavia were malaria-endemic regions. In 1735, Linnaeus wrote about malaria in Sweden in his medical doctorate dissertation: “. . . here there is no illness that is more native. . . nearly all the students in Uppsala are affected by it” (Uppsala-Universitet 2008). In 1946, Reiner Müller reported in his textbook on medical microbiology:

Following the Napoleonic Wars, many of the lowlands in Germany were tainted, and namely stricken with *Tropica* as well; probably due to carriers of gametes returning home from southern theaters of war. Very virulent in the Rhineland in 1826/27 near Duisburg, Grevenbroich, Jülich and Aachen. At the Jülich fort about a quarter of the occupants (soldiers) fell ill as late as 1835. On the west coast of Schleswig Holstein 28 % of the residents fell ill in 1826/27 (Müller 1946).

Overall, European malaria was a widespread parasitosis which, in addition to its endemic prevalence, continued to exhibit epidemic-scale outbreaks and had considerable social and economic significance. While the “non-tropica” forms of malaria resulted in few deaths and chiefly caused morbidity due to periodically recurrent attacks of fever and limited economic achievement potential among those affected, malaria *tropica* claimed countless lives wherever it appeared. The history of the spread of **malaria tropica** in ancient Italy can be traced to about 750 years before Christ (BC). It is believed that the parasite was introduced at that point in time from Africa (Sallares et al. 2004). Malaria *tropica* was decisive in determining settlement patterns throughout the Mediterranean region for more than two millennia. Bruce-Chwatt and de Zulueta write tellingly: “Medieval Italy was no longer the powerful and densely settled land that it had once been during

the classical period. Cities shrank and sometimes disappeared, leaving behind ruins for the modern traveler to ponder in amazement. Expansive areas of fertile land were abandoned” (Bruce-Chwatt and de Zulueta 1980).

An effective drug for the treatment of malaria was not available to people, such that malaria was a totally catastrophic disease among the masses up until the seventeenth century. This changed around the year 1633 with the emergence of imported *Cinchona* tree bark which would turn out to be the first specifically effective antimalarial agent available in Europe. According to the surviving legend, Linnaeus (1701–1778) supposedly named the tree (**genus *Cinchona***) after the

second wife of the Spanish viceroy of Peru, Francisca de Rivera Chinchon, who arrived in Peru in 1629 and was cured by her native Indian servant with the bark of the tree in 1638. This led later to the catchy term “china bark.” *Cinchona* and *Remijia* trees which naturally occur throughout Venezuela and Bolivia. It was the Spanish Jesuits who learned of the fever-reducing effects of the bark extracts from the indigenous people of South and Central America and they [the Jesuits] exported it to Europe (Lee 2002). In Europe, the bark was sold under the names “Peruvian bark”, “china bark”, or “fever bark” as well as “Jesuit’s powder” or “Countess’s powder” (Fig. 1).

Malaria: History of Combating the Disease, Fig. 1 Barks of different *Cinchona* species

The English chemist Robert Tabor (1642–1681) played a very important role in the distribution of the *Cinchona* bark. He performed experiments with it and developed a special technique to extract the quinine it contains; he also propagated its specific antimalarial properties (Lee 2002; Siegel and Poynter 1962). In Italy, the personal physician of the Duke of Modena, Francesco Torti (1658–1741), is credited with first describing malaria as an illness and specifying *Cinchona* bark as a therapeutic agent. Ultimately, the *Cinchona* tree received its official scientific genus name *Cinchona* through none other than the famous Swedish naturalist Linnaeus (1701–1778) in the year 1742 (Linnaeus 1748). He had earned his medical doctorate degree 7 years earlier after writing his doctoral thesis on Swedish malaria, and as director of the Hortus Botanicus in Amsterdam, he also established the taxonomy of Linnaeus for classifying animals and plants which is still in use to this day (Bruce-Chwatt 1988). *Cinchona* bark contains the active ingredient **quinine** which is still an indispensable – synthetically manufactured – malaria medication to this day.

After its discovery, *Cinchona* bark became a scarce and coveted commodity which was only available initially as an import from South America. In his search for local alternatives, the British physician Samuel James (1763–1831) discovered the medicinal effect of salicylic acid in the year 1792. He administered his malaria patients with preparations made with willow bark (*Salix caprea*) which had a bitter taste similar to that of the *Cinchona* bark and was believed to contain the same active ingredients (Fig. 1). James actually observed a fever-reducing effect (Kuhnert 2000; Pierpoint 2007). It was discovered only later that the fever-reducing effect of the willow bark is not based on the destruction of malaria parasites but rather on the effect of the salicylic acid it contains which is the primary ingredient in aspirin; while salicylic acid symptomatically reduces fever, it is not able to destroy malaria parasites.

The sharp increase in the worldwide demand for *Cinchona* bark led to a series of expeditions to the New World of South and Central America, which was little known at that time. The German

botanist Justus Karl Hasskarl (1811–1894) is believed to have been one of the first explorers to bring *Cinchona* tree cuttings and seeds back to Europe from Peru in 1854 at the behest of his Dutch clients (Dünschede 1971). A short time thereafter, Charles Ledger (1818–1906), an English commercial traveler, succeeded in importing 14 English pounds of *Cinchona* seeds to England. Following unsuccessful negotiations with the British government in 1865, these seeds were also ultimately sold to the Dutch (Bruce-Chwatt 1988) who were having massive problems with malaria in their colonies in the East Indies. Thus, it was the Dutch who were ultimately successful in cultivating *Cinchona* trees in their colony of Java and it was discovered that the bark of these trees contains a remarkably high 11–13 % of the active ingredient **quinine**. In honor of Charles Ledger, the trees later received the scientific name *Cinchona ledgeriana*. However, there is a whole series of related species. By 1877 the Javan plantations comprised some 20,000 *Cinchona* trees and the price for their bark hit all-time highs in Amsterdam. While at first the quinine market was being served by the smaller dealers, ultimately the lucrative production of quinine was almost completely in the hands of a few large producers by the end of the nineteenth century; from 1918 onward it was then exclusively controlled by the Dutch (Bruce-Chwatt 1988). It was not until 1929 that **quinine** was completely synthesized by Paul Rabe (1932) and Smith and Williams (2008).

An important milestone in the history of malaria and its prevention was the discovery of the parasite by Charles Louis Alphonse Laveran (1845–1922), a physician at the French military hospital in Constantine (Algeria); in 1880, he noticed spherical bodies in the blood of malaria patients (Bruce-Chwatt and de Zulueta 1980), for which he was to receive a Nobel Prize in 1907. By 1920 the development cycle of the *Plasmodium* parasite in the *Anopheles* mosquito was able to be completely explained. Between 1940 and 1950, the liver stages of the parasite were unequivocally identified in humans as well. The targeted development of medications had not been possible until these processes were fully understood.

Malaria: History of Combating the Disease, Fig. 2 Chemical structures of first synthetic antimalarials

The “Birth” of Synthetic Antimalarial Agents

Due to the Dutch monopoly on quinine and spurred by further developments in chemistry, an intensive search for synthetic antimalarial medications began around 1900. The chemotherapeutic research laboratories of the IG Farbenindustrie AG in Wuppertal-Elberfeld (Germany) were especially active in this field. At first, however, it was only possible to successfully synthesize less potent substances. The lack of a suitable malaria test model was especially limiting with respect to the full-scale systematic testing of new substances. In 1925, Walter Röhl (1884–1923) established the avian malaria model, which had already been described for the first time in 1911 by Phokion Kopanaris (1911). Using this model, scientists ultimately succeeded in discovering the antimalarial effects of **plasmochin** and **atebrine** which entered the market in 1927 and 1932, respectively. With the advent of these two substances, synthetic antimalarial agents superior to quinine were finally available to be produced and these were soon in wide use in the period that followed (Fig. 2).

In 1932, the Dutch East Indian quinine monopoly, alarmed by the success of the German scientists, imposed an embargo on the export of the Java sparrow upon which the avian malaria test model was based (Dünschede 1971). In the event,

Malaria: History of Combating the Disease, Fig. 3 Portrait of Hans Andersag (1902–1955), a Bayer chemist who detected the chloroquine (Resochin®)

however, lab testing was only temporarily halted and by 1934 Hans Andersag (1902–1955; Fig. 3) was able to successfully synthesize **Resochin®** which would later turn out to be the most important antimalarial agent to date.

Resochin® (Chloroquine)

The history of resochin began in June 1934 in the chemotherapeutic research laboratories at IG Farbenindustrie AG in Wuppertal-Elberfeld where Hans Andersag, in the search for new anti-malarial agents, synthesized 4-aminoquinolines. One of the first derivatives to be tested, 2,4-dihydroxybenzoic acid, was shown to be especially effective in the avian malaria model and received the name “resochin” (from the German “**resochinat** des 4-Aminochinolin”). Walther Kikuth (1896–1968), who performed the in vivo testing on the avian model, judged the substance to be similar to **atebrine** in efficacy, but considered it to be somewhat more toxic (Coatney 1983). Franz Sioli (1882–1949) conducted the first resochin trials on humans at the psychiatric hospital in Düsseldorf using paralytic patients who had been treated with *inoculated vivax malaria* (German: *Vivax-Impfmalaria*) which was an established therapy in those days; he observed that the efficacy of the substance was

similar to that of atebrine, but was too toxic for use in humans (Coatney 1983; Dünschede 1971). As a result, this substance was not subjected to any further clinical study and the scientists at Elberfeld concentrated their efforts on the development of a **methyalted resochin**, later named **sontochin** (Coatney 1983). In 1941, resochin and sontochin were licensed to Winthrop Chemical Company in the US (Coatney 1983), where no further clinical advances were made initially. It was not until 1943, when the US government set up the **Board for the Coordination of Malarial Studies** with the goal of developing new antimalarial medications, that the promising effects of resochin were rediscovered, though this occurred via the unintentionally circuitous route of a parallel development of the substance SN-7619 (Coatney 1983). The test substance SN-7619 then received the name **chloroquine**, but it was identical to the previously established **resochin** (Figs. 4 and 5).

From 1946 onward **chloroquine** became available for use in the field of medicine (Haberhorn

Malaria: History of Combating the Disease, Fig. 4 Old packages of the famous chloroquine product Resochin®

Malaria: History of Combating the Disease,
Fig. 5 Old international advertisement for Resochin®

1988). Numerous clinical studies were initiated with chloroquine manufactured by Winthrop and a comprehensive understanding soon emerged that the drug was reliably clinically effective and well tolerated. Starting in 1950 – 5 years after the end of the war – Bayer AG in Leverkusen (Germany) began manufacturing and distributing chloroquine again (Haberkorn 1988). The original chemical name **resochin** became the trade name Resochin® and **chloroquine** became the **chemical name** for the substance.

News of its therapeutic success spread rapidly and a couple of years after its introduction, chloroquine had come into widespread and successful use throughout almost every part of the world where malaria was present (e.g., between 1960 and 1964, it was one of the most widely sold medications). In addition, its long serum half-life (Bayer Healthcare 2008) made it ideal for use as a prophylactic and for the prevention of reinfection in successfully treated patients. In general, chloroquine is considered to be a well-tolerated medication which warrants its widespread use as a treatment and a prophylactic. The number of people who owe their lives to chloroquine has not

been documented. It is believed to be in the hundreds of millions, though this is merely an extremely rough estimate. Nevertheless, some 250 million people are infected with malaria each year, according to current statistics, while twice that number are at risk for infection; this provides a clear picture of the dimension of the malaria problem (WHO 2008).

Chloroquine gained special significance as part of the **WHO Malaria Eradication Program** which begun in 1955 (Greenwood et al. 2008). The plan was to achieve vector control using insecticides, especially DDT. At the same time, all infected persons were to be located and treated in order to destroy the reservoir for the parasites that exists within humans. Chloroquine was the most important therapeutic agent used for the treatment of the masses (Greenwood et al. 2008). The eradication program met with a few successes: by 1982 the WHO was able to declare 24 countries to be endemically malaria free, including the countries of North America and all of Europe. The key to this success was the combined use of the most diverse methods available, for example monitoring wells (Bruce-Chwatt and de Zulueta 1980), which placed high demands on the infrastructure of each country. In this respect, countries with a lower level of development were at a disadvantage. However, the problem of African malaria was so intractable that the WHO was never able to achieve eradication there. However, the actual geographic distribution of malaria is currently far different from the distribution pattern that existed before the eradication program because nearly every malaria-free region has been able to maintain that status.

Effect of Chloroquine (Resochin®)

The **method of action of chloroquine** is based on the disruption of the detoxification function in malaria parasites. *Plasmodium* trophozoites take up large amounts of hemoglobin into their digestion vacuoles during their intraerythrocytic cycle and eliminate the degradation by-product hemozoin, which is toxic to them, by means of polymerization, binding of inert hemozoin crystals, and

presumably through an additional degradation process facilitated by glutathione. Chloroquine binds to hematin gamma-oxodimers and is deposited on the surface of the hemozoin crystals. This ultimately destroys the parasites (Wellems and Plowe 2001).

Chloroquine Resistance

Starting in 1957, the first case reports of **chloroquine resistance** began cropping up (Table 1) for *Plasmodium falciparum* malaria from places as distinct from one another as the Thailand–Cambodia border region and Columbia (Talisuna et al. 2004). Chloroquine resistance has been spreading across the globe ever since. By 1980 nearly all of the endemic regions in South America were affected and the same was true for corresponding countries in Asia by 1989. Chloroquine resistance occurred for the first time in Africa around 1978 and spread rapidly thereafter across the entire continent in the same way it was

observed to spread elsewhere (Talisuna et al. 2004).

The reasons for the emergence of this resistance are many and they are certain to be due to a combination of different factors. Mutations seem to occur with a combination of the following factors (Knobloch et al. 2003):

1. Uncontrolled long-term regimens (for preventive treatment) often associated with low doses of the active ingredient.
2. Travel activity by the person being treated (resulting in the spread of nonsensitive strains).
3. Frequent feeding by *Anopheles* mosquitoes from different hosts, resulting in the local spread of resistant parasites.
4. Simultaneous emergence of different resistance genes.
5. The mutated parasites appear in the blood of the host in greater numbers than the sensitive parasites, resulting in a higher parasite load within the vector.
6. The chaos of wars and the lack of malaria controls also result in the spread of these kinds of resistant strains as soon as they emerge.

Malaria: History of Combating the Disease, Table 1 Characteristics of the stages of chloroquine resistance (RI–RIII)

Stage	Parasitological parameters following treatment	Clinical characteristics
Sensitive	Blood remains free of parasites	Clinically cured (ACR or adequate clinical response)
R I	Following parasite-free interval of 7–28 days for parasite recrudescence	Clinical symptoms return
R II	Reduction in the parasite count by more than 75 % after 48 h, but the parasites are still visible for at least 7 days	Clinical symptoms remain (ETF or early clinical treatment failure)
R III	Reduction in the parasite count by less than 75 % after 48 h	Clinically severe symptoms due to treatment failure (LTF or late treatment failure)

Unlike *Plasmodium falciparum*, in many countries the *Plasmodium malariae* and *P. ovale* species are still almost completely sensitive to chloroquine. The same is true for *Plasmodium vivax* in most of the regions where it occurs. Thus, chloroquine is still an invaluable tool for prevention and treatment in malaria regions where *Plasmodium falciparum* is not endemic.

The emergence of chloroquine resistance had a dramatic impact on malaria mortality rates in many countries. It has been shown that the malaria mortality rates in many regions of West Africa increased twofold to eightfold with the emergence of chloroquine resistance (Trape et al. 1998). Infants and children were especially affected by this increase in mortality.

It was able to be proven that the accumulation of chloroquine decreases in the digestion vacuole of chloroquine-resistant *Plasmodium* strains (Wellems et al. 2001), which indicates resistance mutations in transport proteins. The pfert gene is

localized to chromosome 7 and coded for PfCRT (*Plasmodium falciparum* chloroquine-resistant transporter protein), a transmembrane protein in the digestion vacuoles of *P. falciparum*. Several mutations of this gene have since been identified that result in a resistance to chloroquine. There are well-known mutations of the pfcr gene, for example, from numerous regions in Africa, Asia, and South America (Wellems and Plowe 2001).

Similarly associated with chloroquine resistance are **mutations of the pfmdr1 gene** (*Plasmodium falciparum* multidrug resistance gene 1) on chromosome 5, which is coded for the Pgh1-gene product. Mutations of this gene locus are found in the chloroquine resistances of *P. falciparum* strains, for example, in Mali, Gambia, Sudan, Thailand, or Brazil. In 1993, Malawi was the first African country to switch to sulfadoxine-pyrimethamine as the drug of first choice for the treatment and prevention of malaria because of its high-resistance rates to chloroquine (Laufer et al. 2006). Chloroquine is practically no longer used in Malawi, such that the chloroquine selection pressure on *Plasmodium* parasites dropped sharply.

Eight years after the switch from chloroquine to sulfadoxine-pyrimethamine, Kublin et al. (2001) studied the persistence of the pfcr T76 mutation, which had previously been widespread in Malawi, and they made a shocking discovery: the mutation had disappeared from nearly every isolate they analyzed. However, since there was still some uncertainty as to whether chloroquine would now be sufficiently clinically effective, a prospective randomized study was conducted on 210 patients with uncomplicated **malaria tropica** to compare chloroquine versus sulfadoxine-pyrimethamine. In fact, the therapeutic efficacy for chloroquine was shown to be 99 %, while sulfadoxine-pyrimethamine was only effective in just 21 % of the cases (Laufer et al. 2006). This study proved that it was possible to achieve nearly complete chloroquine sensitivity just 8 years after the total discontinuation of chloroquine use in Malawi. Similar observations on the restoration of chloroquine sensitivity for *P. falciparum* have since been made as well as in Tanzania, South Africa,

Malaria: History of Combating the Disease, Table 2 Characteristics and dosing instructions for Resochin®

Active ingredient	Chloroquine <i>N</i> -(7-chloroquinolin-4-yl)- <i>N</i> , <i>N</i> -diethyl-pentane-1, 4-diamine Latin: <i>Chloroquinum</i>
Chemical formula	C ₁₈ H ₂₆ ClN ₃
CAS number	54-05-7 50-63-5 (diphosphate)
PubChem	2719
DrugBank	DB 00608
ATC code	PO 1 BA 01
Appearance	White or almost white hygroscopic crystalline powder (diphosphate)
Class	Antiprotozoals
Proprietary names	Resochin®, Chlorochin®, Nivaquin®, Weimerquin®
Molar mass	319.88 p mol-1
Melting point	289 °C
pKa value	10.1
Solubility	Water: 10.6 mg/l at 25 °C Not readily soluble in ethanol and methanol (diphosphate)
LD ₅₀	330 mg/kg body weight in rats (oral administration)
Dosing instructions (where sensitivity still exists) according to the German Summary of Product Characteristics for Resochin® tablets, 250 mg and Resochin® junior tablets, 81 mg (Bayer Healthcare 2008)	Preventive treatment: (a) <i>Adults</i> : 500 mg chloroquine phosphate, two tablets (250 mg each) per week (b) <i>Children</i> : 8.1 mg chloroquine phosphate/kg body weight per week (maximum dose of 500 mg/week) <i>Duration</i> : 1 week prior to 4 weeks following a stay in a malaria region Emergency treatment (adults and children): Begin treatment with 16 mg chloroquine phosphate/kg, after 6 h take 8 mg chloroquine phosphate/kg, for the next 2–3 days take 8 mg chloroquine phosphate/kg once daily, microscopy analysis is absolutely necessary (smears/thick blood films)

China, and Thailand (Read and Huijben 2009). Apparently Malawi was not an isolated case. These observations gave rise to the hope that it might be possible to restore chloroquine sensitivity in other regions by means of targeted *drug cycling*, thus ensuring that chloroquine will once again become available as a reliable and inexpensive antimalarial medication for the treatment of malaria *tropica* in the future. It remains unclear how effective the implementation of such a *drug cycling* concept will ultimately be and whether it can be applied to other antimalarial medications as well. But one thing is for sure, chloroquine – once again – is playing a pioneering role.

Characteristics and Dosing Instructions for Resochin® (Chloroquine)

Resochin (Figs. 4, 5) exhibits the following characteristics in Table 2.

For recent treatment besides Resochin®, see ► *Plasmodium* species, therapy, and antimalarial drugs, and Quinghaosu.

Malaria: Immune Responses

Caroline Lin Lin Chua
Department of Medicine (Royal Melbourne Hospital), The University of Melbourne, Parkville, VIC, Australia

Protection of the infected host is measured via two parameters: protection against disease and protection against parasitaemia. The acquisition of natural immunity seems to be able to completely protect the host against disease, but is ineffective against eliminating parasites from the host. This is evidenced by reports of asymptomatic malaria infections, which are rather common in regions with high malaria transmission.

Premunition in High Transmission Areas

Multiple re-infections and frequent exposure to malaria can lead to the generation of some protective immunity. This can partially explain why nonimmune travelers are more susceptible to malaria compared to those living in malaria endemic regions. It is intriguing, however, that even individuals in holoendemic (where transmission occurs all year long) and hyperendemic (where high transmission occurs but only during certain seasons) regions do not develop a sterile immunity against malaria (Obi et al. 2010). These individuals may still be chronically infected with *P. falciparum*, but the grade of parasitaemia is below the level that will cause severe host

morbidities. This type of nonsterilizing immunity is described as premunition and allows for the host and parasite to co-exist without severely compromising one another. Acquiring premunition against malaria does not guarantee life-long protection against malaria disease; this mechanism of protection can be rapidly lost if the individual is not challenged with *P. falciparum* at least once a year (Obi et al. 2010). Some individuals with premunition may be asymptomatic, where malaria infection is likely to go undetected and untreated. Harboring parasites asymptotically may allow for development of partial immunity, which benefits the hosts. For example, it was shown that children who were asymptomatic parasite carriers were less likely to develop clinical episodes in subsequent malaria season (Males et al. 2008). However, these individuals serve as reservoirs for the parasites, resulting in continuous malaria transmission (Fig. 1).

Protective Immunity in Malaria

Malaria-infected hosts can generate a wide range of immune responses to malaria parasites and/or parasite antigens. Host antibody response is one of the most important components of protective immunity in malaria. Antibodies against sporozoites can prevent progression to the blood stages of the parasite life cycle, thus limiting disease as well as transmission. Development of this specific immunity is dependent upon the level of malaria transmission and age; adults living in high transmission areas generally have the highest level of sporozoites-specific antibodies (Greenwood 1990).

Infected hosts can also generate antibodies against various components of the blood stage forms, including merozoites. These antibodies may serve a number of functions, such as blocking the invasion of uninfected erythrocytes, preventing vasculature adhesion, and promoting host cellular responses such as phagocytosis. Whether it is naturally acquired immunity or a vaccine-induced immunity against blood stage *Plasmodium*, a major hindrance to the development of effective host protection is the huge

Malaria: Immune Responses, Fig. 1 Host immunity as a determinant of malaria clinical outcomes. Host immune response induced during malaria infection is an important determinant of disease progression. This

simplified diagram is representative of malaria disease progression in individuals who are either immune or nonimmune to malaria

diversity of antigens that can be displayed by malaria parasites. This is attributed to both antigenic diversity (presence of many distinct parasite strains) and antigenic variation (ability of a single parasite strain to switch to different phenotypes, such as expressing different *var* genes that encode PfEMP-1).

Individuals who have not been exposed to malaria are dependent upon their innate immunity for protection against malaria. However, their inability to mount a malaria-specific response compared to individuals who have developed adaptive immunity may predispose the nonimmune hosts towards severe disease manifestations. For instance, only selective antibodies from malaria immune hosts were able to act cooperatively with monocytes to inhibit parasite growth (Bouharoun-Tayoun and Druilhe 1992). The lack of these immune factors in nonimmune

individuals compromise their ability to limit parasite replication and because parasites are not cleared efficiently, host innate immunity continues to be activated, and dysregulated responses may eventually predispose to immunopathology.

Immunopathology in Malaria

Excessive and dysregulated host immune responses may predispose to malaria-associated pathologies. For instance, host immune factors were implicated in the increased destruction and reduced production of erythrocytes during malaria. The indiscriminate removal of both infected and uninfected erythrocytes from the circulation significantly reduces the number of host erythrocytes. Macrophage inhibitory factor (MIF) and tumor necrosis factor (TNF)- α , which are

immune mediators capable of suppressing erythropoiesis, were found at increased levels in malaria-infected hosts (McDevitt et al. 2006). A balance between pro- and anti-inflammatory cytokine levels is crucial for the host to efficiently clear parasites with minimal host damage; failure to achieve this balance ultimately leads to pathology. Often, high levels of pro-inflammatory cytokines are associated with more severe manifestations of malaria.

During malaria infection, host immune cells are recruited and retained within the site of infection. In cerebral and placental malaria, leukocytes accumulate within the site of parasite sequestration, which are the brain vasculature and the intervillous spaces, respectively. The presence of high density of leukocytes and infected erythrocytes within the usually narrow compartments may result in physical blockage and compromise the physiological functions of these organs. During cerebral malaria, platelets, macrophages, and endothelial cells have all been proposed to contribute to the inflammatory cascade in the brain, causing severe clinical outcomes including coma and long-term neurological consequences. In mice models of cerebral malaria, blocking specific host responses can confer protection against this potentially fatal consequence of malaria (Srivastava et al. 2010; Sun et al. 2003), again suggesting a role of host immunity in pathology.

Malaria: Monocyte/Macrophage Activities

Caroline Lin Lin Chua
Department of Medicine (Royal Melbourne Hospital), The University of Melbourne, Parkville, VIC, Australia

Immunopathology in Malaria

Many clinical consequences of malaria have been attributed to immunopathology. Inflammation is necessary to limit and resolve an infection, yet dysregulated and excessive inflammatory reactions can lead to extensive host damage, sometimes greater than that caused by infection alone. Monocytes/macrophages and their inflammatory products have been implicated in malaria pathogenesis, leading to clinical disease (Fig. 1).

Dysregulated Cytokine Response

Some malaria-infected hosts are unable to generate an early pro-inflammatory response to keep the infection under control. This may be attributed to innate host genetic characteristics or modulation by the malaria parasites. For example, inherent genetic traits, such as polymorphism in the promoter of IL12B gene, can lead to reduced IL-12 production. In children in Tanzania, this was associated with increased mortality risk due to cerebral malaria (Morahan et al. 2002). While cytokines can assist malaria infection clearance, excess pro-inflammatory cytokine production can

Malaria: Monocyte/Macrophage Activities, Fig. 1 Mechanisms by which monocytes/macrophages and their inflammatory products can lead to malaria immunopathology

also contribute to pathology, particularly the development of severe malaria. The levels of IL-12, IL-6, TNF- α , IL-10, and IL-1ra were significantly higher in children with severe manifestations of malaria. An early study showed that the blocking of IFN- γ via antibodies can also prevent the development of cerebral malaria in mice models (Grau et al. 1989), implying a role for

this molecule in immunopathology. In vivo, high levels of IFN- γ have been associated with cerebral malaria (Lyke et al. 2004) and low birth weight (Fried et al. 1998). Platelet factor-4, an initiator of pro-inflammatory response, is known to activate monocytes, and the abolition of this protein expression prevented the development of cerebral malaria. A lower ratio of IL-10/TNF- α has been

associated with severe anemia in children who were living in a holoendemic malaria region. In these individuals, low IL-10 levels may have led to host inability to downregulate pro-inflammatory responses, causing chronic inflammation that is linked to immunopathology.

Indiscriminate Removal of Erythrocytes and Impaired Erythropoiesis

Severe malarial anemia (SMA) is defined as having a hemoglobin concentration of $<50 \text{ g L}^{-1}$ or a hematocrit of <0.15 . The incidence of severe malarial anemia is more frequent in areas of high malaria transmission and most likely to affect children in their early stages of life. SMA causes between 190,000 and 974,000 deaths annually among children under the age of 5 (Murphy and Breman 2001). Similarly, SMA during pregnancy presents a high mortality burden, approximately 20,000 maternal deaths related to SMA per year (Desai et al. 2007).

The pathogenesis of SMA is still not completely understood, but interestingly, this clinical complication does not correlate with parasitemia level, suggesting that clearance of infected erythrocytes alone cannot explain the massive loss of erythrocytes in SMA. It has been reported that during malaria infection, uninfected erythrocytes are also indiscriminately removed from the circulation and at a higher level compared to infected erythrocytes, at a ratio of 8.5:1 (Jakeman et al. 1999). During erythrocyte invasion by merozoites, parasite proteins are deposited on erythrocyte membrane and remain on the surface even when attempted invasion is unsuccessful. One of these proteins is the ring surface protein-2 (RSP-2), which is found on the surface of uninfected erythrocytes as well as on erythroid precursor cells in the bone marrow of anemic malaria patients (Douki et al. 2003; Layez et al. 2005). This modification, together with reduced deformability in both infected and uninfected erythrocytes, increases the susceptibility of these cells to be cleared by host immune mechanisms such as splenic clearance and

phagocytosis. Apart from increased erythrocyte clearance via phagocytosis, monocytes/macrophages can also produce inflammatory mediators such as TNF- α and MIF, which can lead to suppression of erythropoiesis (Johnson et al. 1990; McDevitt et al. 2006). The synergistic action of both increased clearance of erythrocytes coupled with defective production of new erythrocytes from the bone marrow may underlie the pathogenesis of SMA.

Leukocyte and Parasite Accumulation and Disruption of Organ Functions

P. falciparum can be circulated to the brain and placenta, where they sequester to prevent clearance by the spleen. This results in the production of chemotactic molecules which attract host effector cells (usually monocytes, macrophages, and neutrophils) to the site of parasite sequestration; the local inflammation, however, was often associated with poor clinical outcomes. In cerebral malaria, the recruitment and retention of host leukocytes, together with infected erythrocytes, can lead to mechanical blockage in brain microvasculature. This in turn can cause coma and other cerebral abnormalities. Similarly, active recruitment of monocytes/macrophages to malaria-infected placentas can result in the blockage of maternal intervillous spaces and contribute to impaired maternal-fetal material transport and exchange (Umbers et al. 2011). Within these spaces, activated monocytes/macrophages can further release pro-inflammatory mediators that disrupt normal placental functions such as angiogenesis and chemokines that further recruit maternal monocytes to sustain the placental inflammation.

Malaria: Most Common Symptoms

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

Malaria shows a very broad spectrum of symptoms of disease. Geston et al. (2008) listed the most common ones.

Symptoms	Frequency of occurrence (%)
Fever (>38 °C)	97 (96–98)
Shivers	78 (75–80)
Headache	74 (72–76)
Sweating	64 (60–67)
Myalgia	34 (31–37)
Nausea	27 (23–30)
Vomiting	27 (23–30)
Splenomegalia	25 (23–27)
Coughing	20 (17–23)
Diarrheas	18 (17–20)
Hepatomegalia	14 (12–17)
Abdominal pain	13 (11–15)
Icterus	9 (7–10)
Dehydration	6 (3–9)
Bloody stool	3 (1–5)

Malaria: Placental Insufficiency

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This effect inside malaria-infected pregnant women leads often to fetal growth restriction being based on the facts of deterioration in placental function, thus ending in a decrease in transplacental transfer of oxygen and nutrients.

Malariacidal Drugs

Animal Diseases

Hepatozoonosis of Dogs

The protozoan *Hepatozoon canis* (► [Hepatozoon](#)) has been diagnosed in dogs throughout the world and is transmitted by the brown dog tick, *Rhipicephalus sanguineus* (► [Ticks](#)). Clinical hepatozoonosis may be accompanied by concurrent **diseases** caused by other hematropic parasites such as ► [ehrlichiosis](#) (*Ehrlichia canis* belonging to intracellular bacteria of fever-group rickettsiae), babesiosis (*Babesia canis*, *B. gibsoni*), leishmaniasis (*Leishmania infantum*, *L. chagasi*), canine distemper (a viral infection), or dirofilariasis (► [Dirofilaria immitis](#)). A distinct clinical syndrome involves fever, chronic myositis, debilitation, and death. Treatment of hepatozoonosis is problematic; **toltrazuril** (► [Coccidiocidal Drugs](#)), at 5 mg/kg b.w., orally, every 12 h for 5 days may reduce signs of pain, stiffness, and fever so that the initial response to the drug seems excellent. However, the drug failed to prevent relapses, i.e., intracellular schizonts, and cysts are still present during clinical remission. The action of **imidocarb** dipropionate (► [Babesiocidal Drugs](#)) seems to be inferior to toltrazuril; the drug exhibits moderate effect on *H. canis* and cholinergic side effects in dogs. A combined administration of **clindamycin** and the DHFR/TS inhibitors **trimethoprim** sulfate (antifolates: dihydrofolate reductase/thymidylate synthase inhibitors), and **pyrimethamine** hydrochloride (Table 1), given orally for 14 days, may result in remission of clinical signs; relapses were evident within 3–4 months. The antimalarial drug **primaquine** (Table 1) also appears to be effective against *H. canis* infection. Palliative treatment with nonsteroidal, anti-inflammatory drugs will relieve fever and signs of pain in affected dogs.

Leucocytozoonosis of Poultry

Leucocytozoon occurs in cells of various organs and the blood, e.g., erythrocytes and leukocytes; ► [Simulium](#) flies and other arthropods transmit

them. *L. smithi* in turkeys, *L. caulleryi* in chickens, or *L. simondi* in geese or ducks may cause death and thus economic loss in the poultry industry in Japan and other countries of Southeast Asia. Though antimalarial drugs (Table 1) have only a limited curative effect they can be used prophylactically (e.g., pyrimethamine plus sulfonamides). A few anticoccidial drugs as meticlorpindol or halofuginone in combination with furazolidone (► [Coccidiocidal Drugs](#)) may exhibit some activity against the parasites when used prophylactically.

Malaria of Birds, Rodents, and Monkeys

► [Plasmodium](#) of birds occurs in erythrocytes and cells of the reticulohistiocytary system (RHS). Culicine ► [mosquitoes](#) transmit the parasites. Though avian plasmodia infect birds all over the world, clinical signs are infrequently seen. In Europe, *P. relictum* may occur in songbirds and water birds. ► [Malaria](#) of birds caused by *P. gallinaceum* or *P. juxtannucleare* has only limited veterinary importance. The disease may occasionally produce anemia and high mortality in domestic fowl or turkeys and occur in subtropical and tropical areas, particularly in Southeast Asia or southern parts of the USA. Antimalarial drugs, which can be used against avian malaria parasites are listed in Table 1.

For many years avian malaria has played an important role in malaria research as the model of choice for screening of antimalarial drugs prior to the discovery of rodent *Plasmodium* spp. Because the biology of avian malaria differs considerably from that of mammals, various rodent models (e.g., *P. berghei*, *P. yoelii*, or *P. chabaudi* infecting mice, rats, and other rodents) met with great interest. These malaria parasites are uncomplicated and easy in handling and available all over the world. The biology of rodent malaria is very similar to that of human malaria parasites, particularly *P. falciparum*, so that results obtained by drug screening in these models have a certain predictive value for the antimalarial activity of drugs against human parasites. Recently, the *in vitro* cultivation of *P. berghei* has been further optimized now offering new possibilities in molecular screening but also more insight into the

Malariaicidal Drugs, Table 1 Classification of antimalarial drugs according to the stages of *Plasmodium*-affected

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
MALIGNANT TERTIAN MALARIA	<i>Plasmodium falciparum</i> infection can be fatal during initial attack; repeated attacks are due to recrudescence (= renewed manifestation of infection due to the survival of erythrocyte forms); the infection seldom exceeds 1 year			
BENIGN TERTIAN MALARIA	<i>P. vivax</i> / <i>P. ovale</i> infection; repeated attacks are due to recrudescence (see above) or relapses, i.e., renewed manifestations of an infection originating from exoerythrocytic stages of the parasite; the infections die out within 3–4 years			
QUARTAN MALARIA	<i>P. malariae</i> infection; recrudescence originate from chronic undetectable erythrocytic infection; the latter tends to persist for many years			
there are no drugs acting directly against sporozoite of <i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> ; sporozoites inoculated by female mosquitoes during blood meal temporarily circulate in blood, and then enter liver cell to undergo schizogony				
DRUGS ACTING ON PRIMARY TISSUE STAGES IN THE LIVER (TISSUE SCHIZONTICIDES)				
current use of these agents (with the exception of primaquine) is principally in conjunction with an appropriate blood schizontocidal drug for radical cure of chloroquine-resistant <i>P. falciparum</i> strains and other malarials; primaquine may be used for short-term prophylaxis of malaria, e.g., in G-6-PD normal, nonpregnant, visitors to malarious areas; there are new primaquine analogues of interest				
<i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> (effect against <i>P. malariae</i> unknown) (failed when used against some chloroquine-resistant strains)	primary tissue schizonts Hypnozoites (liver parenchyma cells = hepatocytes)	8-aminoquinolines causal prophylactic action prevents vivax and falciparum malaria (for more detail see Table 2: prevention of relapses)	primaquine (*Malirid, others) (chiefly used for radical cure of vivax and ovale malaria) (see antirelapse drugs below)	much less active against erythrocytic stages than tissue stages; adverse effects may be methemoglobinemia (NADH methemoglobinemia
			reductase deficiency), risk of intravascular haemolysis in G6PD-deficient patients (African or Caucasian type); for interaction with quinacrine see → Giardiasis/Man/Therapy	
<i>P. cynomolgi</i> (rhesus monkey), <i>P. berghei</i> , and <i>P. yoelii</i> spp. (rodent malaria, mice)	primary tissue schizonts hypnozoites (liver parenchyma cells = hepatocytes)	8-aminoquinoline analogues causal prophylactic and radical curative drug	tafenoquine has been developed by Walter Reed Army Institute for Research, Washington DC	activity compared to primaquine: about >13 times as hypnozoitocidal drug (<i>P. cynomolgi</i>), >10 – 90 times as blood schizontocidal drug (<i>P. berghei</i>); it may have utility for the treatment of falciparum malaria
<i>P. vivax</i>	primary tissue schizonts hypnozoites (liver parenchyma cells = hepatocytes)	8-aminoquinoline analogues causal prophylactic and radical curative drug clinical investigations are under way	bulaquine = elubaquine has been developed by Central Drug Research Institute, Lucknow, India	may have utility for the treatment of vivax malaria; though not as potent as tafenoquine, it is claimed to be significantly less toxic than primaquine
<i>P. falciparum</i> (<i>P. vivax</i> : fleeing inhibitory action on exoerythrocytic (EE) forms only)	primary tissue schizonts (hepatocytes)	biguanides (antifolate Type 2) has been used for causal prophylaxis; drug-resistant plas- modia limited its use	proguanil (*Paludrine) (= chloroguanide) chlorproguanil (*Lapudrine)	currently used only in combination with sulphas (see below) or other antimalarials (e.g., chloroquine) for chemoprophylaxis of malaria; very well
			tolerated drugs, show tendency to provoke resistance, which was widely reported	

(continued)

Malariacidal Drugs, Table 1 (continued)

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
EE forms of human malaria (parasites are believed to be affected by the drug)	primary tissue schizonts (hepatocytes)	diaminopyrimidines (antifolate Type 2) interferes with dihydrofolate reductase; drug shows tendency to provoke resistance	pyrimethamine (*Daraprim, others) used only in combination with sulphas (see below) pyrimethamine may cause skin rashes, megaloblastic anaemia (at higher doses), in rats, evidence of teratogenicity	prophylactic use of combinations may be obsolete because of widespread drug resistance and potential severe adverse effects;
EE forms of human malaria (parasites possibly affected by sulphas)	primary tissue schizonts (hepatocytes)	sulphonamides sulfones	sulfadoxine (*Fanasil) sulfalene (*Longum) dapsone (used in combinations only, see above)	in rodent plasmodia sulphas exhibit definite causal prophylactic activity at somewhat higher doses than for blood schizontocidal activity
<i>P. falciparum</i> (action on EE forms of other species of human malaria has been inadequately investigated) tetracyclines are active against EE stages of <i>P. vivax</i> in chimpanzees	primary tissue schizonts (hepatocytes) doxycycline has been recommended for chemoprophylaxis	tetracyclines (causal prophylaxis is not advised on general principles) (may be used for nonimmune patients in areas with high prevalence of multidrug-resistant <i>P. falciparum</i>)	doxycycline (*various) <i>P. falciparum</i> infections in conjunction with quinine only; hypersensitivity reactions: erythema multiforme, antibiotic-associated colitis; tetracyclines discolor teeth in growing children	use is strictly limited to <i>treatment</i> of multiresistant
DRUGS ACTING ON LATENT TISSUE STAGES OR HYPNOZOITES IN THE LIVER (ANTIRELAPSE DRUGS):				
are used in conjunction with an appropriate blood schizontocidal drug to achieve a radical cure of <i>P. vivax</i> and <i>P. ovale</i> infection; primaquine is the prototypical drug to prevent relapse caused by hypnozoites; pyrimethamine may also reveal some of this type of activity against <i>P. vivax</i>				
<i>P. vivax</i> , <i>P. ovale</i> highly active during relapse or during latency against latent tissue stages	hypnozoites (hepatocytes) gametocytes see below (erythrocytes)	8-aminoquinolones clinical trials under way	primaquine (PMQ) (*Malirid, others) radical cure of benign tertian malaria tafenoquine (GSK) elubaquine (= bulaquine)	tissue schizontozide preventing relapse with poor effect on blood schizonts; for toxicity see under drugs with causal prophylactic action; PMQ interaction with quinacrine see → Giardiasis/Man/ Therapy
DRUGS ACTING ON ASEYAL BLOOD STAGES (BLOOD SCHIZONTOCIDES):				
used for clinical or suppressive cure; these agents interrupt erythrocytic schizogony and terminate clinical attacks (clinical cure)				
<i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> clinical cure of all types of human malaria	aseyual blood stages: ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	4-aminoquinolines (rapidly acting) had replaced older schizontocides as treatment of choice for of all types of human malaria susceptible to the drug	chloroquine; (*Resochin, others) chloroquine resistance seems to have selective advantage and stability, and is consistently high in East Africa, Western	provides simple treatment and effective safe suppressive prophylaxis generally well tolerated after the oral route; following long-term administration there may be skin lesions

Malariacidal Drugs, Table 1 (continued)

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
<i>P. falciparum</i> , <i>P. malariae</i> : cure of infections by suppressive action of 4-aminoquinolines	4-aminoquinolines have no effect on primary EE forms or latent EE forms		Pacific, and Southeast Asia	and ocular damage as reversible
		4-aminoquinolines (rapidly acting) (close analogue of chloroquine) may be effective against some chloroquine-resistant <i>P.</i> <i>falciparum</i> strains	amodiaquine (*Basoquin, *Amodiaquine, others) there are reports of resistant <i>P. falciparum</i> in Brazil, Pakistan, and elsewhere and cross- resistance between chloroquine and amodiaquine	neuroretinitis; side effects are common but moderate at curative doses; some individuals may show a high degree of intolerance showing superior antimalarial activity over chloroquine; it can cause frequent neutropenia, which may be associated with severe agranulocytosis and toxic hepatitis in one of every 220–1,700 users
amodiaquine is not recommended as first-line treatment of uncomplicated falciparum malaria; its potent toxicity renders it unsuitable (contraindicated) for chemoprophylaxis (see column 4)				
<i>P. falciparum</i> (chloroquine- or mefloquine-resistant strains) in the 50s, quinine has widely been replaced by chloroquine for the radical cure of <i>P. falciparum</i> or <i>P. malariae</i> infections, and for treatment of acute <i>P. vivax</i> or <i>P. ovale</i> infections	asexual blood stages: ring stage, trophozoite, schizonts containing merozoites (erythrocyte) quinine is structurally similar to the other quinolines, especially to mefloqu - ine, see below	chinchona alkaloids (rapidly acting) not suitable for causal prophylaxis quinidine (D-stereoisomer of quinine; may be used for treatment of severe <i>P. falciparum</i> malaria because of its greater antimalarial action than quinine)	quinine (*various) has its origins in Peru in the early 17th century; drug has remained an effective antimalarial for 350 years infusion, p.o.); “general protoplasmic poison”, relatively toxic in therapeutic doses: hypersensitivity reactions, intravascular hemolysis; hemoglobinuria, anuria (blackwater fever); agranulocytosis; abortion (overdose), asthma, tachycardia, CNS symptoms, ocular toxicity, tinnitus	old-timer, now used increasingly in the therapy of falciparum malaria resistant to chloroquine, mefloquine, and other drugs (i.m., i.v.:
<i>P. falciparum</i> sulphas may produce clinical cure of falciparum malaria; asexual blood forms of other human malaria parasites seem to be less affected by them; sulphas should not be used alone because of rapid development of drug resistance in plasmodia	asexual blood stages: ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	sulphonamides (slow acting) sulfones (slow acting); because of their slow action sulphas must be administered with other synergistic acting antimalarials	sulfadoxine (*Fanasil) sulfalene (*Longum) dapson (various) may be used in therapy of uncomplicated <i>P. falciparum</i> malaria resistant to chloroquine in combination with pyrimethamine	antifolate Type 1, which blocks incorporation of PABA to form dihydrofolic acid; potentiating effect with pyrimethamine, a Type 2 inhibitor, (see causal prophylactics, above); sulphonamides can cause hypersensitivity reactions (Stevens-
			Johnson type), agranulocytosis; sulphas may rarely cause hemolysis and methemoglobinemia in D6PD-deficient patients (see primaquine); teratogenicity risk	
<i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> drugs should be combined with chloroquine or	asexual blood stages: ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	biguanides (slow acting) antifolate Type 2 (see above) treatment of acute malarial attack is not recommended	proguanil (*Paludrine) (= chloroguanide) chlorproguanil (*Lapudrine); drugs may be used as a	biguanides are usually used as causal prophylactics (see above) combined with rapidly acting drugs to retard occurrence of

(continued)

Malariacidal Drugs, Table 1 (continued)

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
amodiaquine because their clinical response is slow; cross- resistance with pyrimethamine may occur	primary tissue schizonts (hepatocytes)	*Lapdap (GSK) fixed dose combination for treatment of uncomplicated falciparum malaria (see also Table 2)	partner with other drugs in treating chloroquine-resistant falciparum malaria, e.g., with dapsone (*Lapdap)	drug resistance; proguanil may quickly induce resistance in <i>P. falciparum</i> ; <i>P. vivax</i> has also been reported to be resistant to biguanides
<i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> have widely been used drugs; they may be used for standby treatment only and may cause suppressive (radical) cure in <i>P. falciparum</i> infection	asexual blood stages: ring stage, trophozoite, schizonts containing merozoites (erythrocyte) primary tissue schizonts (hepatocytes)	diaminopyrimidines (slow acting) widespread occurrence of plasmodia resistant to pyrimethamine limited its use as a prophylactic drug though synergy with sulphas should reduce rate of appearance of drug resistance	pyrimethamine combinations: plus sulfadoxine (P/S), (*Fansidar); plus sulfalene (*Metakelfin); plus dapsone (*Maloprim) combinations can cause neutropenia and agranulocytosis and Stevens Johnson syndrome, other serious adverse reactions	P/S has previously been used extensively for prevention of malaria but is no longer effective in Southeast Asia, South America, and Africa; an effective treatment; for nonsevere malaria is the most important malaria control strategy in Africa and elsewhere
<i>P. falciparum</i> (other human malarial parasites have not been adequately documented)	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	tetracyclines (slow acting) potent antibacterial agents; use should be restricted	doxycycline (various) (concurrent use with quinine for treatment of multiresistant falciparum malaria)	tetracyclines discolor teeth in growing children; skin toxicity; photosensitivity; hepatotoxicity in high doses; is contraindicated in pregnancy and children < 8-years old
		macrolide antibiotic (slow acting) potent antibacterial agents; use should be restricted	clindamycin (concurrent use with quinine for treatment of multiresistant falciparum malaria)	lincomycin derivative, side effects may be allergic reactions, diarrhea (enterocolitis, ulcerous colitis), hepatotoxicity, occasionally hypotension, ECG changes
BLOOD SCHIZONTICIDES ACTING ON MULTIDRUG-RESISTANT FALCIPARUM MALARIA				
<i>P. falciparum</i> has developed resistance to chloroquine, sulpha/pyrimethamine combinations and, to some extent, quinine effective in the treatment of severe and complicated disease; chloroquine resistance of various levels is now common in all endemic countries of Africa, and in many of them, particularly in eastern Africa, high levels of resistance pose increasing problems for the provision of adequate treatment; among the countries with endemic falciparum malaria, only Central America and the Caribbean appear to have no serious problems with chloroquine resistance; mefloquine and halofantrine, which have been introduced in the 1980s are effective against multidrug-resistant strains of <i>P. falciparum</i> are being used increasingly for the treatment and prevention (especially mefloquine) of falciparum malaria in many parts of the world, particular Southeast Asia ; since then there have been reports of decreasing sensitivity and resistance to both these drugs and to the structurally related quinine; in some areas, such as on the Thai/Cambodian and Thai/Myanmar borders, high levels of resistance to mefloquine led to the introduction of artemisinin derivatives in 1993; treatment failure rates in children with acute falciparum malaria after administration of high-dose mefloquine (25 mg/kg) had exceeded 50%; examples that parasites may lose their resistance after discontinuing use of chloroquine have been observed in Thailand and Hainan, China				

(continued)

Malariacidal Drugs, Table 1 (continued)

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
<i>P. falciparum</i> resistant to chloroquine and antifolates <i>P. vivax</i> (other human malarial parasites) as with prophylaxis women reported more side effects than men; patients with recrudescence infection following initial *Lariam treatment were at > 7-fold increased risk of severe neuropsychiatric reactions when treated again with high-dose mefloquine 25 mg/kg	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte) ineffective against EE forms in liver	4-quinolinemethanols (rapidly acting) a prospective study of nonserious adverse effects in 3,673 patients with acute falciparum malaria revealed that high-dose mefloquine was well tolerated when given as a split dose	mefloquine (*Lariam); combinations with pyrimethamine and sulfadoxine (*Fansimef) *Lariam as prophylaxis (250 mg/week, starting 1 week before departure) should not be recommended for short-term travellers (up to 3 weeks) because of possible sub-suppressive drug concentration	mefloquine is a therapeutic and suppressive prophylactic drug that should be reserved for treatment of multiple drug-resistant falciparum malaria; side effects may be frequent vertigo, lightheadedness, nausea, GI and visual disturbances, nightmares, headache, insomnia, occasional confusion, and rare psychosis, convulsion, paresthesias, hypotension, and coma
<i>P. falciparum</i> (other human malarial parasites)	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte) ineffective against EE forms in liver	9-phenanthrene-methanols (rapidly acting) have potent blood schizontocidal activity but bioavailability is variable; should not be used in combination with drugs known to prolong QTC interval	halofantrine (*Halfan) there was partial cross-resistance with mefloquine (warning see Table 2)	has been used for treatment (or standby medication) of acute malaria of children and adults (today obsolete); can cause severe (fatal) cardiac arrhythmia as serious prolongation of QTc and PR interval; interaction with mefloquine leads to further prolongation of QT interval (contraindication)
the herb <i>Artemisia annua</i> L. (sweet wormwood, annual wormwood) has been used for many centuries (over 2000 years) in Chinese traditional medicine as treatment for fever and malaria. In 1971, Chinese chemists isolated from the leafy portions of the plant the substance (crude ether extract) responsible for medicinal action; qinghaosu's poor solubility stimulated Chinese scientists to synthesize more soluble derivatives by the formulation of dihydroqinghaosu (DHQHS); its secondary hydroxy group (-O-H) provides the only site that has been used for derivatization; etherification or esterification of DHQHS led to artemether and artesunate, respectively, and other derivatives; all these derivatives proved to be more effective against plasmodia than the parent compound and seem to be the most rapidly acting of all antimalarial compounds developed so far; the spectrum of activity in all derivatives is similar to that of the parent compound qinghaosu or artemisinin; the efficacy of artemisinin and its derivatives against multiple-drug-resistant <i>P. falciparum</i> has been shown in Southeast Asia, sub-Saharan Africa				
artemisinin-based combination therapies on malaria treatment (ACTs): WHO recommends (Jan. 2006, Facts on ACTs) in countries experiencing resistance to conventional monotherapies (e.g., chloroquine, amodiaquine or sulfadoxine-pyrimethamine = SP) to use combination therapies, preferably those containing artemisinin derivatives (ACTs) for falciparum malaria: 1) artemether/lumefantrine, 2) artesunate plus amodiaquine (areas: cure rate of amodiaquine >80%), 3) artesunate plus mefloquine (insufficient safety data to recommend its use in Africa), and 4) artesunate plus SP (areas: cure rate of SP >80%; Note: amodiaquine plus SP is considered as an interim option where ACTs cannot be made available, provided that efficacy of both drugs is high; there are other ACTs in clinical development (see below, and MMV = Medicines for Malaria Venture websites)				
<i>P. vivax</i> and <i>P. falciparum</i> the most striking results achieved with QHS and	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte EE forms	sesquiterpene lactones (very rapidly acting) (QHS bears a peroxide	qinghaosu (QHS) (=O) = artemisinin (micronized; sparingly soluble in oil and water) Chinese	in 1987 approved for marketing in China; recrudescence rate in <i>P. vivax</i> and <i>P. falciparum</i> patients

Malariaicidal Drugs, Table 1 (continued)

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
<i>P. berghei</i>	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	carbonates (very rapidly acting) experimental drug	[–O–C(=O)–O–alkyl or aryl] (oil solubility is similar to that of esters; a-epimer predominates in the products)	most potent derivatives against <i>P. berghei</i> in mice; no detailed study of their therapeutic properties has been published
<i>P. falciparum</i>	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	artelinic acid (very rapidly acting) fill an experimental drug, which has no clear benefits over other artenusate and artemether; it has a lower rate of neurotoxicity than arteether and artemether but is more toxic (×3) than artesunate	–OCH ₂ –(phenyl) COOH i.v. formulations	has been developed by Walter Reed Army Institute for Research (WRAIR) as the most water-soluble drug of this group
<i>P. falciparum</i> Malarone appears to be a safe drug during pregnancy and in children; fixed-dose combination is licenced for treatment of uncomplicated malaria and prophylaxis of <i>falciparum</i> malaria	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	hydroxy- naphthoquinone plus biguanide	atovaquone (*Mepron, GSK) plus *Matarone, GSK *Mepron is also used to treat and prevent <i>Pneumocystis carinii</i> <i>pneumonia</i>	used as a monotherapy, 30% of patients showed recrudescence; coadministration of atovaquone and proguanil revealed synergistic antiplasmodial activity and a dramatic effect on cure rates of patients with <i>falciparum</i> malaria
<i>P. falciparum</i> to date, no resistance to ACTs has been reported in patients; if used alone, the artemisinins will cure <i>falciparum</i> malaria in 7 days, ACTs will produce high cure rates in 3 days with higher adherence to treatment; for more information see Facts on ACTs (WHO websites)	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte)	fluorene derivative (racemate) synthesized by Institute of Military Medical Sciences (IMMS), Beijing in the 1970s, registered as antimalarial drug in China in 1987 *Coartem belongs to the essential drugs (WHO list)	benflumetol plus artemether (*Coartem or *Riamet, Novartis); the ACT may cause up to 95% cure rates in children in Africa infected with multiresistant strains of <i>P. falciparum</i> (also standby therapy for travellers)	lumefantrine is poorly soluble in water and oils but soluble in unsaturated fatty acid (oleic or linoleic acid); the latter was used for oral formulation (tablets, capsules) in clinical studies in China since 1979 and coadministered orally with artemether; preclinical trials showed synergy between the two drugs
<i>P. falciparum</i> a new ACT (pyronacridine plus pyronaridine) for treatment of drug- resistant <i>falciparum</i> malaria	asexual blood stages ring stage, trophozoite, schizonts containing merozoites (erythrocyte) gametocytes (DNA topoisomerase II inhibitor)	benzonaphthyridine synthesized in China in 1970 (acridine-type Mannich base)	pyronaridine tablets, capsules (*Malaridine) combination with artenusate (*Pyramax, Shin Poong Pharm, Korea)	has been used clinically in China since the 1970s and is marketed in that country and Korea, it may have potential as replacement for oral formulations of chloroquine in many areas for treatment of uncomplicated <i>falciparum</i> malaria

DISEASE <i>Plasmodium</i> species (other information)	STAGE AFFECTED (location), other information	CHEMICAL CLASS (other information)	INN (preferable oral route) (*Tradename)	COMMENTS (toxic reactions and other comments)
DRUGS ACTING ON GAMETOCYTES (GAMETOCYTOCIDES)				
may inhibit gametocytogenesis or kill mature gametocytes (sexual erythrocytic stages) of plasmodia, thereby preventing transmission of malaria to mosquitoes; damaging effects on gametocytes include severe alterations of morphology, and a marked decrease in numbers of gametocytes; the only drugs that have the potential to interrupt transmission of falciparum malaria are the 8-aminoquinolines (primaquine, pamaquine, and tafenoquine) and pyronacridine (see above); gametocytogenesis takes place when critical parasite density has been achieved in the blood of host; hence, malaria may be transmitted during the recovery phase of the acute falciparum malaria despite successful eliminating of the asexual stages of the infection by blood schizontocidal drugs having little or no activity against mature gametocytes; patients whose infection recrudesced were nearly 5-times more likely to become gametocyte carrier than those who were treated successfully				
<i>P. falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i>	gametocytes (immature and mature stages) (erythrocyte)	8-aminoquinolines (direct and fast action)	primaquine tafenoquine	only drugs with fast and direct action on gametocytes of <i>P. falciparum</i> ;
				high gametocytocidal action on all species of human malarial parasites, rendering the gametocytes incapable of development in mosquitoes
<i>P. falciparum</i>	gametocides (stage II and III)	benzonaphthylridine	pyronacridine	proved active against young gametocytes <i>in vitro</i>
<i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i>	gametocytes (immature and mature stages) (erythrocyte)	4-aminoquinolines	chloroquine amodiaquine *Flavoquine, others	effective against immature but ineffective against mature gametocytes of <i>P. falciparum</i>
<i>P. falciparum</i>	precursors of sexual stages and early (I–II) gametocytes (erythrocyte)	artemisinin derivatives	artemether , artesunate	do not kill mature gametocytes but reduces transmission of falciparum malaria
DRUGS AFFECTING FORMATION OF MALARIAL OOCYSTS AND SPOROZOITES IN INFECTED MOSQUITOES				
have little or no apparent effect on gametocytes but cause inhibition of subsequent development of sporogonic forms in the mosquito; agents with sporontocidal action can reduce transmission of malaria				
<i>P. falciparum</i> , <i>P. vivax</i> sporogony is inhibited for varying periods (dose dependent)	oocysts (midgut wall of mosquito)	biguanides (highly active) may be valuable for sporontocidal prophylaxis	proguanil (*Paludrine) (= chloroguanide) chlorproguanil (*Lapudrine)	mosquitoes fed on gametocyte carriers receiving therapeutic doses do not develop intact oocysts, i.e., drugs ablate
				transmission of malaria by preventing or inhibiting formation of oocyst and sporozoites in infected mosquitoes; infection to man may be interrupted or decreased
<i>P. falciparum</i> , <i>P. vivax</i> (drug appears to inhibit sporogony)	oocysts (midgut wall of mosquito)	diaminopyrimidines	Pyrimethamine (*Daraprim, others)	no apparent effect on the production, number or morphology of gametocytes
<i>P. berghei</i> (experimental rodent malaria)	oocysts (midgut wall of mosquito)	sulphonamides sulfones	sulfadoxine dapsone	dapsone may cause increased gametocyte production in falciparum malaria; these gametocytes may not be infective to mosquitoes

Data given in this table have no claim to full information. Comments on adverse effects and other properties of drugs cited in this table refer to data from literature, labels of sponsors, suppliers, or manufacturers, and various websites (e.g., WHO, MMV, others)

Abbreviations: INN = International Nonproprietary Names

conventional screening for chemotherapeutic agents. Today, a variety of *in vitro* and *in vivo* models provide a broad basis to investigate a drug's mode of action and potential mechanisms leading to drug resistance in rodent and human malaria. Targets may be malarial hemozoin/ β -hematin supporting hem polymerization or sequence variations in the *P. vivax* dihydrofolate reductase-thymidylate synthase gene and their relationship with pyrimethamine resistance. Owing to improved *in vitro* cultivation techniques, large numbers of different *Plasmodium* developmental stages may be helpful to find out new chemotherapeutic targets. One of these targets is the cytoplasmic ribosomal RNA of *Plasmodium* spp., as it seems to be quite different from the mechanisms in other eukariotic cells. Macaque monkeys are now used extensively not only for ► [AIDS](#) research but also malaria research, involving rhesus monkeys (*Macaca mulatta*) compared to other macaque species (*M. fascicularis*). Rhesus monkeys are highly susceptible to most of the malarias (especially *P. knowlesi*, *P. coatneyi*, and *P. fragile*, distinctively less *P. cynomolgi*, *P. fieldi*, and others) whereas *M. fascicularis* is not. So a comparison of response to malaria in susceptible rhesus monkey and resistant *M. fascicularis* might be a good starting point. Molecular-genetic studies on their hemoglobins and innate red blood cell polymorphisms would be probably of more value than research on immunity to *P. falciparum* in such artificial hosts as owl monkeys, *Aotus* and *Saimiri*.

Malaria of Humans

Clinical Forms

Malaria is a mosquito-borne infection caused by four species of obligate intracellular protozoan parasites of the genus *Plasmodium* of which *P. vivax* is the most common and *P. falciparum* the most pathogenic. Each species has distinguishing morphological characteristics and the disease caused by each is also distinctive. *P. vivax* occurs north and south of the Equator within the 15–16 °C summer isotherms whereas *P. falciparum* is limited to, but widely distributed

in, the tropics and subtropics, particularly Africa and Asia. *P. falciparum* causes “Falciparum or malignant tertian malaria” (incubation time 7–14 days), the most dangerous form of human malaria. It can produce a foudroyant infection in nonimmune individuals that, if not treated, may result in rapid death. If treated early, the infection usually responds to appropriate antimalarial drugs in chloroquine-sensitive or chloroquine-resistant areas, and recrudescence will not occur. If treatment is inadequate, however, recrudescence of infection may result from multiplication of parasites in the blood. Delay in treatment, especially in patients already having parasites in the blood for a week or so, may lead to irreversible state of shock, and death may occur though the peripheral blood is free of parasites. *P. vivax* causes ‘Vivax or benign tertian malaria’ (incubation time 12–17 days, sometimes several months or >1 year); the disease produces milder clinical attacks than those seen in falciparum malaria. It has a low mortality rate in untreated adults and is characterized by relapses, which may occur as long as 2 years after primary infection. *P. ovale* causing “Ovale or benign tertian malaria” (incubation time 16–18 days or longer) occurs primarily in tropical Africa (especially in West Africa) and in some endemic areas of New Guinea and the Philippines and Southeast Asia. Clinical manifestations are similar to that of *P. vivax* infections (including periodicity and relapses), but are more readily cured. *P. malariae* causing “Quartan malaria” (incubation time 18–40 days) is not found below the 16 °C summer isotherms and has a variable and spotty distribution in the tropics and subtropics. Clinical signs are similar to that of “benign tertian malaria,” the febrile paroxysm occurring every 72 h. Symptomatic recrudescence can occur several years after primary infection and is due to persistent undetectable parasitemia, and not due to ► [hypnozoites](#) as in case of *P. vivax* infections.

Biology

Though malaria can be transmitted by transfusion of infected blood, humans are naturally infected by **sporozoites** inoculated by the bite of female anopheline ► [mosquitoes](#). Sporozoites rapidly leave the circulation and initiate ► [schizogony](#)

in the parenchymal cells of the **liver** (so-called preerythrocytic or exoerythrocytic = EE stage of infection), which is asymptomatic and lasts for 5–16 days depending on the *Plasmodium* spp. In *P. falciparum* and *P. malariae* infections primary tissue schizonts burst simultaneously within a certain period, leaving no parasite stages in the liver. In *P. vivax* and *P. ovale* infections, some tissue parasites remain “dormant” (latent forms or hypnozoites) before they proliferate and produce relapses of erythrocytic infection months to years after primary infection.

Mature tissue schizonts rupture in the liver thereby releasing thousands of merozoites; thence, they enter the circulation, and invade erythrocytes (erythrocytic stage or cycle of infection). In red blood cells, parasites undergo asexual development from young ring forms to trophozoites and then to mature schizonts that release several merozoites after erythrocytes being ruptured more or less synchronically. This process produces the febrile clinical attack. The released merozoites invade other naive erythrocytes to continue the cycle, which may proceed until death of the host or interruption by antimalarials or modulation by acquired immunity will occur. Some erythrocytic parasites differentiated into sexual forms, male microgametocytes and female macrogametocytes.

During the blood meal, the female mosquito ingests gametocytes, and syngamy (fertilization of the macrogamont by a microgamont) occurs in the mosquito's gut. The resulting sedentary zygote transforms to a motile ookinete. Ookinetes are specialized cells able to actively leave the packed blood bolus and invade the mosquito midgut epithelial tissue to reach the hemolymph side and develop as oocyst. In the oocyst, the parasites multiply to sporozoites, which later invade the salivary gland and are subsequently inoculated into another human host during blood meal. Ookinete motility, secretion of chitinase, resistance to the digestive enzymes, and recognition/invasion of the midgut epithelium all may play crucial roles in the transformation to oocyst. A number of target ookinete-stage antigens are currently on the list of malaria transmission-blocking vaccines, and monoclonal antibodies to

both Pfs25 and Pfs28 block oocyst development. Pfs25 is at the initial stage of human trials.

Global Control Programs

The **prevalence** of malaria is increasing, and in 1998, more patients suffered from malaria than in 1958. According to the World Health Organization (WHO), more than 500 million people are infected with malaria parasites each year and more than 2 million – mostly **children** living in sub-Saharan Africa – die of it. These often quoted figures of malaria-related deaths per year among African children under the age of 5 years originated from analyses of malaria transmission intensities in sub-Saharan Africa, which are typically 1 or 2 orders of magnitude greater than those that occur in most other malaria-endemic regions of the world. With the attainment of age- and exposure-acquired protective immunity, there is a rapid decline in the incidence of malaria infection associated with high clinical tolerance and virtually no case fatalities after the ages of 10–15 years. In south Asian regions malaria **transmission intensities** are not only typically much lower than those in much of tropical Africa, leading to a very different age distribution of disease, but the health systems for managing the malaria problems are also substantially different. Rapid case treatment appears to be the most suitable measure to save lives at risk under virtually all circumstances of malaria transmission. Where effective early treatment is the main tool in reducing malaria mortality, the emergence of **resistance to antimalarial drugs** is a major concern. High levels of resistance (RIII), especially to drugs such as chloroquine, pyrimethamine-sulfadoxine, and mefloquine (Fansidar, Fansimef, Table 1), for example, in Vietnam, have been associated with increases in malaria-related deaths. Meanwhile, drug resistant strains of *P. falciparum* are spreading to new territories, including India, South America, and the Far East; also the *Anopheles* mosquito vector is gaining greater resistance to insecticides. Antimalarial drugs such as chloroquine, antifolates, and mefloquine (Table 2) are becoming frequently less effective against *P. falciparum* and *P. vivax*, the principal infectious agents of malaria. To successfully tackle these serious problems, **malaria**

Malariacidal Drugs, Table 2 Treatment and prevention of malaria in humans

Nonproprietary name	Brand name other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments (for adverse effects of drugs see also Table 1)
Malaria parasites: <i>Plasmodium falciparum</i> (malignant tertian malaria), <i>P. vivax</i> , <i>P. ovale</i> (benign tertian malaria), <i>P. malariae</i> (quartan malaria)		
TREATMENT OF CHLOROQUINE-RESISTANT FALCIPARUM MALARIA		
chloroquine-resistant <i>P. falciparum</i> occur in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistance has been reported in Yemen, Oman, Saudi Arabia, and Iran); a detailed guide to the management and treatment of different forms of malaria is given in 'Practical Chemotherapy of Malaria'		
atovaquone plus proguanil	drugs of choice: *Mepron (GSK) *Paludrine (Wyeth Ayrest, Astra Zeneca) adverse effects may be oral ulceration, hair loss, scaling of palms and soles, urticaria, rare: hematuria: (large doses), vomiting, abdominal pain, diarrhea (large doses), thrombocytopenia	atovaquone: 1,000 mg qd $\times$ 3d; *11–20 kg: 250 mg; 21–30 kg: 500 mg; 31–40 kg: 750 mg; adverse effects may be frequent rash, nausea, and vomiting, occasionally diarrhea proguanil: 400 mg qd $\times$ 3d; *11–20 kg: 100 mg; 21–30 kg: 200 mg; 31–40 kg: 300 mg; occasional
atovaquone/proguanil (A/P) should not be given to pregnant women	*Malarone (GSK, Cascan) dose regimen for adults: 1g A/400 mg P, single dose daily for 3d; pediatric dose is based upon body weight	Malarone: atovaquone/proguanil may be available outside the USA in a fixed dose combination tablet (250 mg atovaquone/100 mg proguanil for adults; pediatric tablets: 62.5 mgA/25 mg P)
quinine sulfate plus doxycycline or tetracycline (TC)	drugs of choice (many manufacturers) dose/regimens for TC: 250 mg qid $\times$ 7d; *6.25 mg/kg qid $\times$ 7d	quinine: 650 mg q8h $\times$ 3–7d; *30 mg/kg/d in 3 doses $\times$ 3–7d; in Southeast Asia, relative resistance to quinine has increased and the treatment should be continued for seven days doxycycline: 100 mg bid $\times$ 7d; *4 mg/kg/d $\times$ 7d (slow acting drug); drug is contraindicated in pregnancy and in children less than 8 years old; doxycycline can cause GI disturbances, vaginal moniliasis (candidiasis), and photosensitivity reactions
quinine sulfate plus clindamycin contraindications: quinine: G-6-PD deficiency, optic neuritis, tinnitus, history of blackwater fever, pregnancy, thrombocytopenic purpura	drugs of choice many manufacturers	quinine: 650 mg q8h $\times$ 3–7d; *30 mg/kg/d in 3 doses $\times$ 3–7d; in Southeast Asia, relative resistance to quinine has increased and the treatment should be continued for 7 days clindamycin: adult and children: 20 mg/kg/d in 3 doses $\times$ 7d; side effects may be allergic reactions, diarrhea (enterocolitis, ulcerous colitis), hepatotoxicity, occasionally hypotension, ECG changes
quinine sulfate plus pyrimethamine-sulfadoxine do not use if you are: • allergic to pyrimethamine • pregnant or breast feeding • or you have kidney or liver/ blood problems (anemia due to folate deficiency) • or patient is <2 months of age	alternatives: (many manufacturers) *Fansidar (Roche) it may cause low blood sugar in diabetes patients; common side effects are diarrhea, dizziness, headache, nausea, vomiting	quinine: 650 mg q8h $\times$ 3–7d; *30 mg/kg/d in 3 doses $\times$ 3–7d; in Southeast Asia, relative resistance to quinine has increased and the treatment should be continued for 7 days Fansidar: 3 tablets at once on the last day of quinine; *<1 year: ¼ tablet; 1–3 yrs: ½ tablet; 4–8 yrs: 1 tablet; 9–14 yrs: 2 tablets; Fansidar tablets contain 25 mg of pyrimethamine and 500 mg of sulfadoxine; resistance to pyrimethamine-sulfadoxine has been reported from Southeast Asia, the Amazon basin, sub-Saharan Africa, Bangladesh, and Oceania
ALTERNATIVE DRUG REGIMENS FOR TREATING MULTIDRUG-RESISTANT FALCIPARUM MALARIA		
for treatment of multidrug-resistant <i>P. falciparum</i> in Southeast Asia, especially Thailand, where resistance to mefloquine and halofantrine is frequent, a 7-day course of quinine and tetracycline is recommended, artesunate plus mefloquine, artemether

Malariacidal Drugs, Table 2 (continued)

Nonproprietary name	Brand name other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments (for adverse effects of drugs see also Table 1)
plus mefloquine or mefloquine plus doxycycline are also used to treat multiple-drug-resistant <i>P. falciparum</i> ; at a single high dose (1250mg) of mefloquine for adults (see below), adverse effects including nausea, vomiting, diarrhea, dizziness, disturbed sense of balance, toxic psychosis, and seizures can occur; mefloquine is teratogenic in animals and has not been approved for use in pregnancy; mefloquine prophylaxis appears to be safe when used during the second half of pregnancy and possibly during early pregnancy as well; it should not be given together with quinine or quinidine, and caution is required in using quinine or quinidine to treat patients with malaria taken mefloquine for prophylaxis; in the USA and elsewhere, the pediatric dosage has not been approved by government regulatory agencies; this may be also true for other alternative drugs as doxycycline, clindamycin, or atovaquone, including the adult dosage		
mefloquine	*Lariam (Roche)	mefloquine: 1250 mg once (750 mg followed 12 hours later by 500 mg); *25 mg/kg once (15 mg/kg followed 8–12 hours later by 10 mg/kg (< 45 kg b.w.); tablets: in the USA, = 250 mg = 228 MEF base, other countries 275 mg = 250 mg MEF base; resistance to MEF has been reported in some areas, such as the Thailand-Myanmar border, where 25 mg/kg should be used (adverse effects see Table 1)
halofantrine Warning: it is not recommended for use in combinations with drugs or clinical conditions known to prolong QTc interval or in patients who have received mefloquine or known or suspected ventricular dysrhythmias	alternatives: *Halfan (GSK) Warning: there have been rare reports of serious ventricular dysrhythmias sometimes associated with death, which may be sudden; should be prescribed only by physicians who have special competence in diagnosis and treatment of malaria	halofantrine: 500 mg q6h × 3 doses; repeat in 1 week; *8 mg/kg q6h × 3 doses (< 40 kg); repeat in 1 week; halofantrine may be effective in multiple-drug-resistant <i>P. falciparum</i> malaria, but treatment failures and resistance have been reported; in adults and children, a single 250 mg dose can be used for repeat treatment in mild to moderate, there is variability in absorption; thus it should not be taken 1 hour before and 2 hour after meals because food increases its absorption; cardiac adverse reactions may be lengthening of PR and QTc intervals and fatal cardiac arrhythmias and is contraindicated in patients with cardiac conduction defects (cardiac monitoring is recommended)
atovaquone plus doxycycline	alternatives: *Mepron many manufacturers	atovaquone: 1000 mg qd × 3d; *11–20 kg: 250 mg; 21–30 kg: 500 mg; 31–40 kg: 750 mg; adverse effects may be frequent rash and nausea, occasionally diarrhea
		doxycycline: 100 mg bid × 3d; *2 mg/kg/d × 3d (slow acting drug); drug is contraindicated in pregnancy and in children less than 8 years old; doxycycline can cause GI disturbances, vaginal moniliasis (candidiasis), and photosensitivity reactions
artesunate plus mefloquine	alternatives: Guilin No. 1 Factory, Guangxi, China (Mepha, Aesch Basle Switzerland/Vietnam) *Lariam (Roche)	4 mg/kg/ × 3d (adult and pediatric dose); very rapidly acting drug, which may occasionally produce ataxia, slurred speech, neurological toxicity, possible increase in length of coma in severe falciparum malaria, increased convulsions, prolongation of QTc interval; for artesunate formulations see Table 1
mefloquine: 1,250 mg once (750 mg followed 12 hours later by 500 mg) (adverse effects see Table 1) *15 mg/kg followed 12 hours later by 10 mg/kg		
TREATMENT OF CHLOROQUINE-RESISTANT VIVAX MALARIA		
<i>P. vivax</i> with decreased susceptibility to chloroquine has been reported in Papua-New Guinea, Indonesia, Myanmar, India, Irian Jaya, and the Solomon Islands		
quinine sulfate plus doxycycline	drugs of choice many manufacturers	quinine: 650 mg q8h × 3–7d; *30 mg/kg/d in 3 doses × 3–7d; in Southeast Asia, relative resistance to quinine has increased and the treatment should be continued for 7 days
		doxycycline: 100 mg bid × 7d; *4 mg/kg/d in 2 doses × 7d (slow acting drug); drug is contraindicated in pregnancy and in children less than 8 years old; doxycycline can cause GI disturbances, vaginal moniliasis (candidiasis), and photosensitivity reactions

(continued)

Malariacidal Drugs, Table 2 (continued)

Nonproprietary name	Brand name other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments (for adverse effects of drugs see also Table 1)
mefloquine (for other side effects see Table 1)	drug of choice *Lariam (Roche) at this dosage there is increased risk for still birth; therefore, it should not be used for treatment of malaria during pregnancy	mefloquine: 750 mg followed 12 hours later by 500 mg; *15 mg/kg followed 8–12 hours later by 10 mg/kg (<45kg b.w.); tablets: in the USA, = 250 mg = 228 mefloquine (MEF) base, other countries 275 mg = 250 mg MEF base; resistance to MEF has been reported in some areas, such as the Thailand-Myanmar border, where 25 mg/kg should be used (adverse effects see Table 1)
quinine sulfate plus pyrimethamine-sulfadoxine	drugs of choice *Fansidar (Roche) Fansidar: 3 tablets at once on the last day of quinine; *<1 year: ¼ tablet; 1–3 yrs: ½ tablet; 4–8 yrs: 1 tablet; 9–14 yrs: 2 tablets; Fansidar tablets contain 25 mg of pyrimethamine and 500 mg of sulfadoxine; resistance to the combination has been reported from Southeast Asia, the Amazon basin, sub-Saharan Africa, Bangladesh, and Oceania	quinine: 650 mg q8h × 3–7d; *30 mg/kg/d in 3 doses × 3–7d; in Southeast Asia, relative resistance to quinine has increased and the treatment should be continued for 7 days
chloroquine plus primaquine	alternatives: many manufacturers	chloroquine: 25 mg base/kg in 3 doses over 48 hours; *25mg base/kg in 3 doses over 48 hours; primaquine: 30 mg base daily × 14d; *0.6 mg/kg/d × 14d; African, Asian and Mediterranean peoples, patients should be screened for glucose-6-phosphate dehydrogenase deficiency to prevent hemolytic anemia; it should not be used during pregnancy
TREATMENT OF ALL PLASMODIA (except chloroquine-resistant <i>P. falciparum</i> and <i>P. chloroquine</i> resistant <i>vivax</i> , see above)		
CHLOROQUINE-SENSITIVE AREAS		
chloroquine-resistant <i>P. falciparum</i> occur in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistance has been reported in Yemen, Oman, and Iran; <i>P. vivax</i> with decreased susceptibility to chloroquine has been reported Papua-New Guinea, Indonesia, Myanmar; India, Irian Jaya, and the Solomon Islands)		
chloroquine (phosphate) ORAL ROUTE (uncomplicated or mild malaria may be treated with oral drugs)	drug of choice *Aralen , *Resochin , many others (many manufacturers)	1g (600 mg base), then 500 mg (300 mg base) 6 hours later, then 500 mg (300 mg base) at 24 and 48 hours; *10 mg base/kg (max. 600 mg base), then 5 mg base/kg 6 hours later, then 5mg base/kg at 24 and 48 hours; if chloroquine is not available, hydroxychloroquine sulfate is as effective; 400 mg hydroxychloroquine sulfate is equivalent to 500 mg chloroquine phosphate; occasional adverse effects may be pruritus, vomiting, headache, confusion depigmentation of hair, skin eruption, corneal opacity, exfoliative dermatoses, eczema, myalgias, photophobia; rare side effects are irreversible retinal injury (may occur when total dosage exceeds 100 grams), nerve-type deafness, peripheral neuropathy and myopathy, heart block, blood dyscrasias, hematemeses (vomiting of blood)
ALL PLASMODIA (ESPECIALLY SEVERE FALCIPARUM MALARIA)		
exchange transfusion may be helpful for some patients with high-density (>10%) parasitemia, altered mental status, pulmonary edema, or renal complications		
quinidine gluconate PARENTERAL ROUTE or	drug of choice	10 mg/kg loading dose (max. 600 mg) in normal saline slowly over 1–2 hours, followed by continuous infusion of 0.02 mg/kg/min until oral therapy can be started; *same as adult dose;

(continued)

Malariacidal Drugs, Table 2 (continued)

Nonproprietary name	Brand name other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments (for adverse effects of drugs see also Table 1)
	precautions: continuous EKG, blood pressure, and glucose monitoring are recommended, especially in pregnant women and young children; quinidine may have greater antimalarial activity than quinine; thus the loading dose should be decreased or omitted in those patients who have received quinine or mefloquine, if >48 hours of parenteral treatment is required, the quinine or quinidine dose should be reduced by 1/3 to 1/2	
quinine dihydrochloride PARENTERAL ROUTE	drug of choice	20 mg/kg loading dose i.v. in 5% dextrose over 4 hours, followed by 10 mg/kg over 2–4 hours q8h (max 1,800 mg/d) until oral therapy can be started; *same as adult dose; for precautions , which should be taken see quinidine above
artemether PARENTERAL ROUTE (for i.m. use only)	alternative drug *Artenam (Arenco, Belgium, other manufacturers and suppliers)	3.2 mg/kg i.m. then 1.6 mg/kg qd; *same as adult dose; occasional adverse effects may be neurological toxicity, possible increase in length of coma in severe falciparum malaria, increased convulsions, prolongation of QTc interval; precautions: it should not be used in pregnancy and in nursing mothers; for artemether formulations see Table 1; the artemisinin derivative has been produced by Sanofi-Aventis and Kunming Pharmaceutical Factory in China, and the UNDP/World Bank/WHO Special Program for Research and Training in Tropical Diseases (TDR), others
PREVENTION OF RELAPSES		
<i>P. vivax</i> and <i>P. ovale</i> (radical cure of benign tertian malaria) (cf. Table 1: hypnozoites in liver)		
primaquine phosphate (it can be also used for prophylaxis, see below)	drug of choice various manufacturers (in some countries not directly available in pharmacies)	26.3 mg (15 mg base)/d × 14d or 79 mg (45 mg base)/wk × 8 wks; *0.3 mg base/kg/d × 14d; some relapses have been reported with this regimen, especially in strains from Southeast Asia; relapses should be treated with a second 14-day course of 30 mg base/day;
	the drug can cause hemolytic anemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase; this deficiency is most common in African, Asian, and Mediterranean peoples; patients should be screened for G-6-P deficiency before treatment; it should not be used during pregnancy and in lactating women; occasional adverse effects may be neutropenia, methemoglobinemia, GI disturbances, rare are CNS symptoms, arrhythmias and hypertension	
MALARIA PREVENTION		
no drug regimen guarantees protection against malariae; if fever develops within a year, especially within the first 2 months after travel to malarious areas, travelers should be advised to consult a specialist for tropical medicine; insect repellents, insecticide-impregnated bed nets, and proper clothing are important adjuncts for malaria prophylaxis; for prevention of attack after departure from areas where <i>P. vivax</i> and <i>P. ovale</i> are endemic, which includes almost all areas where malaria is found (except Haiti), some experts prescribe in addition primaquine phosphate 26.3 mg (15 mg base) or, for children, 0.3 mg base/kg/d during the last 2 weeks of prophylaxis; others prefer to avoid the toxicity of primaquine (see above) and rely on surveillance to detect malaria cases when they occur, particularly when exposure was limited or doubtful		
PREVENTION IN CHLOROQUINE-SENSITIVE AREAS		
chloroquine-resistant <i>P. falciparum</i> occur in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistance has been reported in Yemen, Oman, and Iran; <i>P. vivax</i> with decreased susceptibility to chloroquine has been reported Papua-New Guinea, Indonesia, Myanmar; India, Irian Jaya, and the Solomon Islands)		
chloroquine (phosphate)	drug of choice *Aralen, *Resochin, many others (many manufacturers and suppliers)	500 mg (300 mg base) once/week; *5 mg/kg base once/week, up to adult dose of 300 mg base; prophylaxis should be started one week prior to travel and continued weekly for the duration of stay and for 4 weeks after leaving; in pregnancy chloroquine prophylaxis has been used extensively
	and safely; the safety of other prophylactic antimalarials in pregnancy is less clear; for this reason, travel during pregnancy to chloroquine-resistant areas (see above) should be considered carefully	

(continued)

Malariacidal Drugs, Table 2 (continued)

Nonproprietary name	Brand name other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments (for adverse effects of drugs see also Table 1)
PREVENTION IN CHLOROQUINE-RESISTANT AREAS		
chloroquine-resistant <i>P. falciparum</i> occur in all malarious areas except Central America west of the Panama Canal Zone, Mexico, Haiti, the Dominican Republic, and most of the Middle East (chloroquine resistance has been reported in Yemen, Oman, and Iran; <i>P. vivax</i> with decreased susceptibility to chloroquine has been reported in Papua-New Guinea, Indonesia, Myanmar; India, Irian Jaya, and the Solomon Islands)		
mefloquine is not recommended for patients with cardiac conduction abnormalities, and patients with a history of seizure or psychiatric disorders should probably avoid mefloquine; resistance to mefloquine has been reported in some areas, such as Thailand; in these areas, doxycycline should be used for prophylaxis; in children <8 years old, proguanil plus sulfafurazole has been used; several studies have shown that daily primaquine provides effective prophylaxis against chloroquine-resistant <i>P. falciparum</i> ; malaria prophylaxis with primaquine was also evaluated in Irian Jaya using 0.5 mg/kg primaquine base daily for 1 year by 126 Javanese men with normal G-6-PD activity; primaquine was well tolerated and effective for prevention of falciparum malaria (94.5%) and vivax malaria (90.4%); for prevention of attack after departure from areas where <i>P. vivax</i> and <i>P. ovale</i> are endemic, which includes almost all areas where malaria is found (except Haiti), some experts prescribe in addition primaquine phosphate 26.3 mg (15 mg base) or, for children, 0.3 mg base/kg/d during the last 2 weeks of prophylaxis; others prefer to avoid the toxicity of primaquine (see above) and rely on surveillance to detect malaria cases when they occur, particularly when exposure was limited or doubtful; atovaquone/proguanil (Malarone; available in the USA, Europe and elsewhere) can be used for oral prophylaxis and treatment of malaria due to blood forms of all human plasmodia, exoerythrocytic forms of <i>P. falciparum</i> , and <i>P. falciparum</i> resistant to pyrimethamine-sulfadoxine = Fansidar (SE Asia, the Amazon basin, sub-Saharan Africa, Bangladesh and Oceania) or mefloquine (significant problem in Thailand along the borders with Myanmar and Cambodia); co-administration of tetracyclines reduces plasma concentrations of atovaquone by 40 to 50%, proguanil has no known drug interactions		
atovaquone/proguanil	drug of choice Malarone or Malarone Pediatric (GSK)	250 mg/100 mg (1 tablet) daily; *11–20 kg b.w.: 62.5 mg/ 25 mg (1 tablet) daily; 21–30kg: 125 mg/50 mg daily; 31–40kg: 187.5 mg (75 mg daily; >40 kg: 250 mg/100 mg daily beginning 1–2 days before travel and continuing one week after leaving the malaria zone; it is generally well tolerated
mefloquine or	drug of choice *Lariam	250 mg once/week; *<5 kg: no data; 5–10 kg: 1/8 tablet; 11–20 kg: 1/4 tablet; 21–30 kg: 1/2 tablet; 31–45 kg: 3/4 tablet; >45 kg: 1 tablet; tablets: in the USA, = 250 mg = 228 MEF base, other countries 275 mg = 250 mg MEF base; prophylaxis should be started one week prior to travel and continued weekly for the duration of stay and for 4 weeks after leaving; the pediatric dosage has not been approved in the USA and elsewhere, and the drug has not been approved for use during pregnancy; it has been reported to be safe for prophylactic use during the second-half of pregnancy and possibly during early pregnancy as well; however, these may be increased for stillbirth if used for treatment of malaria; women should take contraceptive precautions while taking mefloquine and for 2 months after the last dose
doxycycline or	drug of choice	100 mg daily; *2 mg/kg/d, up to 100 mg/day; drug is contraindicated in pregnancy and in children less than 8 years old; prophylaxis should be started one week prior to travel and continued weekly for the duration of stay and for 4 weeks after leaving; doxycycline can cause GI disturbances, vaginal moniliasis (candidiasis), and photosensitivity reactions
primaquine	alternatives	0.5 mg/kg base daily; *same as adult; the drug can cause hemolytic anemia, especially in patients whose red cells are deficient in glucose-6-phosphate dehydrogenase; this deficiency is most common in African, Asian, and Mediterranean peoples; patients should be screened for G-6-P deficiency before treatment; it should not be used during pregnancy and in lactating women; occasional adverse effects may be neutropenia, methemoglobinemia, GI disturbances, rare are CNS symptoms, arrhythmias and hypertension
chloroquine phosphate plus	alternatives *Aralen *Resochin, others	chloroquine phosphate: 250 mg once/week; *< 5 kg: no data; 5–9 kg: 1/8 tablet; 10–19 kg: 1/4 tablet; 20–30 kg: 1/2 tablet; 31–45 kg: 3/4 tablet; >45 kg: 1 tablet

(continued)

Malariacidal Drugs, Table 2 (continued)

Nonproprietary name	Brand name other information	Adult dosage/*pediatric dosage (mg/kg b.w., or total dose/individual, oral route), miscellaneous comments (for adverse effects of drugs see also Table 1)
pyrimethamine/sulfadoxine (for presumptive treatment) or	*Fansidar (Roche)	Fansidar: carry a single dose (3 tablets) for self-treatment of febrile illness when medical care is not immediately available; * <1 yr: ¼ tablet; 1–3 yrs: ½ tablet; 4–8 yrs 1 tablet; 9–14 yrs 2 tablets; Fansidar tablets contain 25 mg of pyrimethamine and 500 mg of sulfadoxine; resistance to the combination has been reported from Southeast Asia, the Amazon basin, sub-Saharan Africa, Bangladesh, and Oceania
proguanil widely available in Canada; England (not in the USA and elsewhere)	*Paludrine (Astra Zeneca, others)	Proguanil: 200 mg daily; * < 2 yrs: 50 mg/daily; 2–6 yrs: 100 mg/d; 7–10 yrs: 150 mg/d; >10 yrs: 200 mg; proguanil is recommended mainly for use in Africa south of the Sahara; prophylaxis is recommended during exposure and for 4 weeks afterward; proguanil has been used in pregnancy without evidence of toxicity
chlorproguanil/dapsone	*Lapdap (GSK)	fixed dose combination has been introduced in 2003; there is yet no resistance reported, however, up to now there is only limited experience on safety and efficacy
SELF-PRESUMPTIVE TREATMENT		
a traveller can be given a course of atovaquone/proguanil, mefloquine or quinine plus doxycycline for presumptive self-treatment of febrile illness; therefore the drug given should be different from that used for prophylaxis. Self-treatment should be used only if a traveller cannot promptly get to medical care		
atovaquone/proguanil	drug of choice *Malarone (GSK)	4 adult tabs daily × 3d; * < 5 kg: not indicated; 5–8 kg: 2 peds/tabs once/d × 3d; 9–10 kg: 3peds/tabs once/d × 3d; 11–20 kg: 1 adult tabs once/d × 3d; 21–30 kg: 2 adult tabs once/d × 3d; 31–40 kg: 3 adult tabs once/d × 3d; >40 kg: 4 adult tabs once/d × 3d
OR quinine sulfate plus doxycycline OR plus tetracycline OR plus clindamycin	drug of choice *various manufacturers and suppliers	quinine: 650 mg 98 h × 3–7 d; *30 mg/kg/d in 2 doses × 7d; in Southeast Asia treatment should be continued for 7d (increased resistance to the drug) doxycycline: 100 mg bid × 7d; *4mg/kg/d in 2 doses × 7d tetracycline: 250 mg qid × 7d; *6.25 mg/kg qid × 7d clindamycin: 20 mg/kg/d in 3 doses × 7d; *same dosage as adults
mefloquine	alternative drug	mefloquine: 750 mg followed 12 hrs later by 500 mg; *15 mg/kg followed 12 hrs later by 10mg/kg
artesunate plus mefloquine	alternative drugs	artesunate: 4 mg/kg/d × 3d; × same dosage as adults mefloquine: 750 mg followed 12 hrs later by 500 mg; 15 mg/kg followed 12 hrs later by 10 mg/kg

Abbreviations: the letter < d > stands for day (days); *qd* daily (quaque die), *qh* each hour every hour, *qd* each day, every day, *bid* twice daily, *tid* 3 times per day, *qid* 4 times per day (quarter in die), *p.c.* (*post cibum*) after meals

Data given in this Table have no claim to full information. Comments on adverse effects and other properties of drugs cited in this table refer to data from literature, labels of sponsors, suppliers, manufacturers, websites such as Drugs.com, MMV, or others, and The Medical Letter: Drugs for parasitic infections, vol 46 (issue 1189) 2004

research appears to be drastically underfunded compared to other diseases, such as HIV or asthma. It is suggested that the results of research have not been sufficiently exploited. On the other hand, obstacles to better exploitation, according to the survey, include poor orientation of research programs to practical problems and public needs.

Topics having the best prospects for advancing understanding over the next years were the genetics and biology of *Plasmodium* and disease epidemiology. Thus many **vaccine projects** have failed after promising starts and malaria researchers say prospects for a workable vaccine are still a long way off.

The **new global strategy** for malaria control moves away from several outmoded concepts inherited from the times when eradication of malaria still seemed feasible. Particular attention is given to the need for disease-oriented programs, with a reduction of mortality and morbidity. Technical elements of these programs include the provision of **early diagnosis and prompt treatment**, the selective use of sustainable preventive measures, the prevention and control of epidemics, and the strengthening of local capacities in basic and applied research. Some of these issues are development of drug packaging systems at a district level to improve dosing and compliance, better collaboration between public and private sectors to improve case management of malaria particularly childhood illness and improved supervision of drug vendors by district pharmacies. One issue is to replace chloroquine by inexpensive drugs such as pyronaridine and short half-life antifolate drugs (Table 1). Evaluation and development of pyronaridine up to registration including technology transfer to Malaysia was planned targeted year 2000.

► **Vector control** is an essential component of the “Global Malaria Control Strategy,” adopted in 1992. Existing tools for vector control, if appropriately used, can help prevent or reduce the transmission of malaria and other mosquito-borne diseases (e.g., ► **Lymphatic Filariasis**). There are detailed guidelines for the use of four main options: indoor residual spraying; personal protection, including **insecticide-impregnated bednets** and other materials (Table 2/Malaria Prevention), larviciding and ► **biological control**, and environmental management. Thus, efficacy trials with insecticide-treated bednets for preventing childhood mortality are on the track, thereby checking promotion of technology, implementation, definition of areas for bednets use, and cost-effectiveness consideration.

Antimalarial Drug Development

New antimalarial agents (targets) with novel modes of action are urgently needed because of increasing drug resistance of malaria parasites in endemic areas, including cities, and islands. In recognition of this need the WHO/TDR Steering Committee on Drugs for Malaria (CHEMAL,

NIH/NIAID, and MMV = ‘medicines for malaria ventures’) support studies from the identification of new biochemical targets for drug development to the registration of a drug, usually in partnership with a commercial company. **New drug leads** have included selection for development of one lead from 2nd generation peroxidic drugs, phospholipid and antiplasmodial protease (proteinase) inhibitors, or protein prenyl transferase inhibitors. The funding agencies have screened a series of compounds (10 mg quantities) or compound libraries against 3 malaria ► **proteinases**, including 2 aspartic proteinases (plasmeprin I and II, similar to human cathepsin D, and 1 cysteine proteinase, falcipain, analogous to human cathepsin L). For combinatorial libraries, enzymatically active recombinant enzyme may be provided by CHEMAL. In a study, cDNA coding for *P. falciparum* hypoxanthine-guanine-xanthine phosphoribosyltransferase has been cloned in *Escherichia coli* and purified to homogeneity to allow detailed kinetic and structural studies. Significant differences between the human and parasitic enzymes indicate that parasite-specific inhibitors are feasible. ► **Tubulin** as a potential drug target is of interest and several microtubule inhibitors are potent blockers of various stages of development of *Plasmodium*. Most compounds have been derived from anticancer screening programs as cholchicine-site binders (e.g., cholchicine, colcemid, and anthelmintic benzimidazole carbamates, cf. ► **Nematocidal Drugs, Man**), vinblastine-site binders (vinblastine and vincristine), taxoids (taxol, taxotere), and others (*cis*- and *trans*-tubulozole, and trifluralin). Though trifluralin proved much less toxic than the other microtubule inhibitors, indications of carcinogenicity and modest tolerability preclude its development as an antiprotozoal drug.

Currently used drugs (Table 2), particular successors to chloroquine have not always met the expectations left by this remarkable compound characterized by low price, low toxicity, optimal pharmacokinetic properties providing safe prophylactic and therapeutics antimalarial activity against all four species of *Plasmodium* that infect humans. Derivatives of artemisinin and new formulations of them (artemether, arteether, and sodium artesunate, Table 1) with

potent activity against erythrocytic stages of *P. falciparum* and *P. vivax*, which is at least as effective as the parent compound, are on the target list for further clinical development. Applied field research with artemether has been performed in developing countries (and France) for use of the drug in childhood cerebral malaria, and clinical development of injectable (i.m.) arteether is going on with promising results concerning efficacy, tolerability, and pharmacokinetics in patients with severe malaria. Some artemisinin-type compounds (artelinic acid, trioxane, and tetraoxane analogues) and combinations of benflumetol (a fluoromethanol synthesized in China) plus artemether or mefloquine plus artesunate are at an advanced stage of preclinical or clinical development or already in use for chloroquine-resistant *falciparum* malaria. The development of arteflene was discontinued because of a disappointing blood schizontocidal activity against *falciparum* malaria (Table 1). Alternative antifolate combinations with sulfonamides and sulfones exhibiting shorter half-lives than pyrimethamine-sulfadoxine have been studied, e.g., proguanil analogue WR 250417 showing high activity against pyrimethamine-resistant strains of *P. falciparum*. Atovaquone, a hydroxynaphthoquinone (Tables 1 and 2), which has novel mode of action, can be used in coadministration with either tetracycline or proguanil to cure multiresistant *falciparum* malaria. A new 8-aminoquinoline (WR 238605 tafenoquine) proved to be more active but less toxic than primaquine. Several plant (root) extracts isolates in China protected mice against *P. berghei* and *P. yoelli* infections, and revealed shikimate pathway in *P. falciparum* may give some hope to new selective therapeutic options and possibly targeted drug development.

In addition, existing validated targets of antifolates such as pyrimethamine or proguanil (e.g., resistance of *P. falciparum* resulting from point mutations of the DHFR domain of the bifunctional thymidylate synthetase with mutations at residues 51, 59, 108, and 164), and still unknown targets of quinoline antimalarials (e.g., precise mode of action and mechanism of parasite resistance to these drugs are still not completely understood), or several other identified enzymes from a

number of biochemical pathways in *P. falciparum* have been proposed to be potential drug targets, though few of them have been validated. Possibly **new tools and technologies** (e.g., transfection, DNA microassays, and proteomic analysis) and the availability of DNA sequences generated by the Malaria Genome project along with more classic approaches (*in vitro* and *in vivo* screening of compounds) will facilitate the development of new antimalarials as well as the generation of a deeper understanding of the molecular mechanism(s) of drug resistance in malaria.

Malaria-Infected Erythrocyte-Derived Microvesicles (MVs)

Heinz Mehlhorn

Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

In the years since 2010 numerous papers were published showing that the erythrocytes and platelets of humans produce tiny (0.1–1 μm sized) microvesicles as long as an infection with *Plasmodium falciparum* or *P. vivax* is persistent in patients. These microvesicles are produced by blebbing of the host plasma membrane. While in infected patients large numbers of these microvesicles can be found, their number is extremely low in uninfected persons. After antimalarial treatment the high number decreases suddenly, reaching lowest numbers on day 14 after treatment. Similar microvesicles occur in cases of diseases such as cardiovascular disturbance, arthritis, thalassemia or tumor outbreaks. Flow assays by help of antibodies against the parasite antigen RESA (being situated below the host cell membrane in malaria patients) proved that this protein is apparently included inside these microvesicles. Experiments with *Plasmodium berghei* of rodents showed that these MV's introduce inflammatory responses of the host and contribute to pathological effects during malaria. Investigations of Mantel et al. (2013) showed

that the MV's are quantitatively released from infected red blood cells during the cycles of human malaria. Most of the MV's are produced during the late phase of the schizogony in red blood cells and they include portions of the parasites and other proteins. Apparently synchronization of schizont disruption is introduced by these MV's. Thus they play as well a role as messengers between infected red blood cells as they are active as immunostimulating agents, which finally influence the in-time formation of gametocytes of *Plasmodium* species inside red blood cells.

Malarial Parasites

Caroline Lin Lin Chua
Department of Medicine (Royal Melbourne Hospital), The University of Melbourne, Parkville, VIC, Australia

Five *Plasmodium* species have been identified as capable of infecting humans: *P. falciparum*, *P. vivax*, *P. malariae*, *P. ovale*, and *P. knowlesi*. There are differences in the clinical manifestations due to infection by each species. *P. falciparum* is the most deadly species, causing the majority of malaria-associated deaths in the world. It is associated with several severe manifestations of malaria such as cerebral malaria, placental malaria, respiratory distress, and severe malarial anemia. *P. vivax* was previously known as the

“benign” malaria species, but recently there have been reports that this species can also lead to respiratory distress and adversely affect pregnancies. Individuals infected with either *P. malariae* or *P. ovale* generally demonstrate mild symptoms of malaria. However, some patients can remain as asymptomatic carriers, while very rarely, others may develop severe disease. *P. malariae* patients who develop a chronic infection may suffer from nephrotic syndrome, which is characterized by proteinuria, severe generalized edema, and ascites (Hendrickse et al. 1972). *P. ovale* infections can be associated with splenic infarction and splenic rupture (Cinquetti et al. 2010; Imbert et al. 2009). *P. knowlesi* is the most recent human malaria species to be identified. It was previously known as a monkey malaria species, until a large number of zoonotic cases were reported in Sarawak, Malaysia, in 2004 (Singh et al. 2004). *P. knowlesi* infections have been associated with a range of clinical manifestations, from asymptomatic and uncomplicated disease to severe fatal malaria. *P. knowlesi* patients with severe complications show signs of respiratory distress, acute renal failure, hypotension, and hypoglycemia (Daneshvar et al. 2009). Of all these species, relapse malaria cases have only been reported for *P. vivax* and *P. ovale* infections. The relapse cases of *P. ovale* happen less frequently compared to *P. vivax* infections, and the patients are often asymptomatic (Collins and Jeffery 2005). *P. vivax* can form hypnozoites, which are dormant stage parasites in the liver that are responsible for relapse cases. It is still inconclusive if *P. ovale* can similarly develop into hypnozoites to cause relapse. The factors that trigger the reactivation of malaria parasites to cause relapses in both infections are currently unknown.

Malathion

Chemical Class

Organophosphorous compounds (dithiophosphate).

Mode of Action

Acetylcholine esterase inhibitor. ► [Ectoparasitocides: Agonists and Antagonists of Cholinergic Transmission](#), Insecticides, Ectoparasitocidal Drugs.

MALDI-TOF MS

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

This term is an abbreviation of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, which represents a method for the quick identification of 38 Central European culicid species caught in the field (including newly invaded

species such as ► [Aedes albopictus](#) and *Aedes japonicus*. This database is constantly enlarged.

Male-Biased Parasitism

Heinz Mehlhorn
Institut für Zoomorphologie, Zellbiologie und Parasitologie, Heinrich-Heine-Universität, Düsseldorf, Germany

It was often described that male hosts suffer from significantly more parasites of a given species compared to female hosts. It is explained by the theory that androgens have an immunosuppressive effect.

Mallophaga

Group of ► [Lice](#) feeding on skin, keratinous substances of feathers and hairs, and dermal secretion fluids, while ► [Anoplura](#) suck blood. Biting lice (from Greek: *mallos* = Kiefer, *phagein* = eat) are found in the hair of vertebrates and in/on the feathers of birds. Important species are listed in (Table 1) ► [Mallophagidosis](#). Morphologically they can be easily differentiated from bloodsucking ► [Lice](#) by the fact that their head is broader than the breast (thorax) (Figs. 1, 2, 3, 4, and 5, pages 770, 771). In humans Mallophaga are only

Mallophaga, Fig. 1 LM of *Trichodectes canis* (dog)

Mallophaga, Fig. 3 LM of *Werneckiella equi* (horse)

Mallophaga, Fig. 2 DR of *Bovicola bovis* (cattle)

Mallophaga, Fig. 4 SEM of *Stenocrotaphus* sp. (chicken, birds)

Mallophaga, Fig. 5 SEM of *Menopon gallinae* (chicken, birds)

occasionally found in those working with infected animals.

Symptoms of Disease

Itching, loss of hair or feathers.

Mallophagidosis

Disease due to infestation with species of ► [Mallophaga](#), see (Table 1, page 772).

Malnutrition

Symptom mostly seen in children infected with *Giardia*, ► [Ascaris](#), ► [hookworms](#), trichuriasis, marasmus, kwashiorkor.

Malpighamoeba mellificae

These $5 \times 15 \mu\text{m}$ -sized ► [amoeba](#) are found in the intestine of bees. They may show a flagellum, often they introduce diarrhoea, and thus lead to weakening or death of the infected bee. Transmission occurs via cysts (Fig. 1) during feeding of the larvae bees by worker-bees.

Therapy

Unknown.

Malpighi, Marcello (1628–1694)

Italian physician, one of the founders of the scientific microscopy, describer of many parasites, and of the excretory system of insects (Malpighian tubes).

M

Malpighian Tubes

Excretory system of ► [insects](#), ► [mites](#), ► [ticks](#).

MALT

Mucosa associated lymphoid tissue (► [Immune Responses](#)).

Maltese Cross Stage

Dividing stage of small ► [Babesia](#) species (e.g., *B. divergens*) giving rise simultaneously to four merozoites inside the host erythrocytes.

Mallophagidiosis, Table 1 Important Mallophaga and control measurements

Parasite	Host	Vector for	Symptoms	Country	Therapy Products	Application	Compounds
<i>Trichodectes canis</i>	Dog	<i>Dipylidium caninum</i>	Alopecia, eczema, secondary bacterial infections	World-wide	Advantage (Bayer) Defend Just-For-Dogs Insecticide (Schering Plough) Bolfo Flohschutz-Puder (Bayer) Front line (Merial)	Spot on Spray Dermal powdering Spot on	Imidacloprid Pyrethrin + Permethrin + Piperonylbutoxid + N-octyl bicycloheptene dicarboximide Propoxur Fipronil
<i>Felicola subrostratus</i>	Cat	<i>Dipylidium caninum</i>	Alopecia, eczema, secondary bacterial infections	World-wide	Advantage (Bayer) Defend Just-For-Dogs Insecticide (Schering Plough) Bolfo Flohschutz-Puder (Bayer) Elector (Elanco)	Spot on Spray Dermal powdering Pour on	Imidacloprid Pyrethrin + Permethrin + Piperonylbutoxid + N-octyl bicycloheptene dicarboximide Propoxur Spinosad
<i>Bovicola bovis</i>	Cattle		Skin secretion; host-specific; strong reproduction only possible in ill or weak cattle; constant irritation	World-wide	Tiguvon Cattle Insecticide Pour on (Bayer) Elector (Elanco) Asuntol-Puder 1 % (Bayer)	Pour on Dermal powdering Wash, spray	Fenthion Spinosad Coumaphos Phoxim
<i>Bovicola caprae</i>	Goat		Itching, constant irritation	Worldwide	Sebacil Lösung		
<i>Bovicola limbatus</i>	Goat			Rare in Europe			
<i>Lepikentron ovis</i>	Sheep		Itching, wool loss through rubbing	Worldwide	Sebacil Lösung (Bayer)	Wash, spray	Phoxim
<i>Wernerneckiella equi</i>	Horse	Infectious anaemia?	Itching, strong concern, bite, and rubbing wounds	Worldwide			
<i>Lipeurus caponis</i>	Chicken	–	Loss of feathers	Worldwide	Sebacil (Bayer) Mite-Stop (Alpha-Biocrine)		Phoxim neem extract
<i>Menopon gallinae</i>	Chicken	–	Loss of feathers	Worldwide			

***Malpighamoeba mellificae*, Fig. 1** LM of an encysted amoeba with two nuclei from a honey bee

Mammillae

Conical or truncated integumental elevations covering the body and the legs of *Ornithodoros* ticks.

Mandibulata

Classification

Subphylum of ► [Arthropoda](#).

Arthropods with antennae have been placed within the subphylum Mandibulata, thus named because the first postoral appendages are mandibles (► [Arthropoda/System](#)).

Mange Mites

The parasitic ► [mites](#) of the families ► [Sarcoptidae](#) and [Psoroptidae](#) which generally give rise to well-defined dermatoses (► [Skin Diseases, Animals/Arthropods](#), ► [Mange, Animals](#)).

Mange, Animals

Skin disease in animals caused by digging ► [mites](#) such as ► [Sarcoptes](#) spp. which make

funnels in the skin that become inflamed due to secondary bacterial invasion (► [Acariosis, Animals](#)) of other mites (see below).

Cheyletiellosis

See [Table 1](#).

Demodicosis

See [Table 2](#).

Trombiculidiasis

See [Table 3](#).

Otodectic Mange

See [Table 4](#).

Notoedric Mange

See [Table 5](#).

Sarcoptic Mange

See [Table 6](#).

Psoroptic Mange

See [Table 7](#).

Chorioptic Mange

See [Table 8](#).

Psoergatic Mange

See [Table 9](#).

Mange, Animals, Table 1 *Cheyletiella* species

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Cheyletiella yasguri</i>	(young) Dog	Blood loss, dermatitis	Worldwide	Many	Bathing	Pyrethroids
<i>Cheyletiella blakei</i>	(young) Cat			Stronghold	Spot on	Selamectin
				Advocate/ Advantage Multi (Bayer)	Spot on	Moxidectin + Imidacloprid

Mange, Animals, Table 2 *Demodex* species of animals

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Demodex canis</i>	Almost only young Dogs	Local – generalized dermatitis/alopecia	Worldwide	Ectodex (Intervet)	Bathing	Amitraz
				Mitaban pfizer	Bathing	Amitraz
				Advocate/ Advantage Multi (Bayer)	Spot on	Moxidectin + Imidacloprid
<i>Demodex bovis</i>	Cattle	Often subclinic, no itching, pea-sized nodules, leather damages (economic loss)	Worldwide			
<i>Demodex ovis</i>	Sheep	Often subclinic, hardly itching, often round the eyes, vulva and prepuce	Worldwide			
<i>Demodex caprae</i>	Goat		Worldwide (Switzerland, France)			
<i>Demodex equi</i>	Horse	Often subclinic, hardly itching; transfer only from mother to foal; starts at head, then possibly generalization, (secondary bacterial infections)	Worldwide			
<i>Demodex caballi</i>	Horse	Primarily eye (Meibom gland)	Worldwide			
<i>Demodex suis</i>	Pig	Rare; hardly itching, transfer via contact	Worldwide	Point-Guard Miticide/ Insecticide (Intervet)	Pour-on	Amitraz

Mange, Animals, Table 3 Trombiculid species

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Neotrombicula autumnalis</i>	Dog, cat, man , horse, ruminants	Itching, secondary bacterial infections	Worldwide	Kiltix (Bayer)	Collar	Flumethrin/Propoxur
				Bayticol (Bayer)	Spray	Flumethrin
<i>Neotrombicula desaleri</i>	Ruminants	No transfer from contact, transfer from plant to animal; often under the tail (cattle), nose (sheep), ears (goat); red stains	Worldwide			
<i>Neoschöngastia xerothermobia</i>	Ruminants					
<i>Trombicula akamushi</i>	Dog, cat, cattle, man	Rare, itching, secondary bacterial infections	India, Japan, China, Pacific Islands, North Australia			

M

Mange, Animals, Table 4 *Otodectes* species and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Otodectes cynotis</i>	Dog, cat	Ear mange, itching, inflammation, “Otitis externa parasitaria” (ear cancer), sometimes generalized	Worldwide	Ultra Ear Miticide (A.H.A.)	Otic	Rotenone
				Advocate/ Advantage Multi (Bayer)	Spot on	Moxidectin + Imidacloprid

Mange, Animals, Table 5 *Notoedres* species and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Notoedres cati</i>	Cat	Head, all ages, mange symptoms	Worldwide	Stronghold Revolution (Pfizer)	Spot on	Selamectin

Mange, Animals, Table 6 *Sarcoptes* species and control measurements

Parasite	Host	Symptoms	Country	Therapy Products	Application	Compounds
				Advocate/ Advantage Multi (Bayer)	Spot on	Moxidectin + Imidacloprid
<i>Sarcoptes canis</i>	Dog, man	Head, ear (peripheral), ridge of the nose, eye, lower abdomen, area inside the thigh, itching, later hyper- and parakeratosis, secondary bacterial infections	Worldwide	Rotenone Shampoo (Goodwinol)	Shampoo	Rotenone
<i>Sarcoptes bovis</i>	Cattle	Starts often at head, then generalization; alopecia, hyperkeratosis, wrinkling, secondary bacterial infections economic loss	Worldwide	Ivomec 1 % Injection For Cattle (Merial)	Injection	Ivermectin
				Dectomax (Pfizer)	Injection	Doramectin
				Sebacil Lösung (Bayer)	Wash, spray	Phoxim
<i>Sarcoptes ovis</i>	Sheep	Often only head, secondary bacterial infections	Worldwide	Cydecime injectable (Fort Dodge)	Injection	Moxidectin
<i>Sarcoptes rupicaprae</i> (= <i>S. caprae</i>)	Goat	Head mange	Worldwide			
<i>Sarcoptes equi</i>	Horse, man (pseudoscabies)	Starts often at head, then generalization; alopecia, hyperkeratosis, wrinkling, secondary bacterial infections	Worldwide			
<i>Sarcoptes suis</i>	Pig, man (pseudoscabies)		Worldwide	Ivomec 0.27 % Sterile Solution (Merial)	Injection	Ivermectin
				Point-Guard Miticide/ Insecticide (Intervet)	Pour-on	Amitraz
				Sebacil Pour- on (Bayer)	Pour-on	Phoxim

Mange, Animals, Table 7 *Psoroptes* species and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Psoroptes ovis</i> (syn. <i>P. bovis</i>)	Ruminants	Cattle-sheep transfer possible, itching, symptoms see <i>Sarcoptes bovis</i> , large economic significance in sheep	Europe	Co-Ral 25 % Wetttable Powder (Bayer)	Dip or spray	Coumaphos
				Ivomec 1 % Injection For Cattle (Merial)	Injection	Ivermectin
				Dectomax (Pfizer)	Injection	Doramectin
				Sebacil Lösung (Bayer)	Wash, spray	Phoxim
				Cydectin (Bayer)	Injection	Moxidectin
<i>Psoroptes cuniculi</i>	Goat	Ear Mange, often young (>3 weeks) lambs	Worldwide			
	Horse	Ear				
<i>Psoroptes equi</i>	Horse	Primarily in thick hair, protected areas (e.g., beginning of tail, under the mane), itching, symptoms see <i>Sarcoptes bovis</i> , large economic significance in sheep	Worldwide			

M

Mange, Animals, Table 8 *Chorioptes* species and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Chorioptes bovis</i> (Leg mange, tail mange)	Ruminants	Starts often at tail, eat flakes; foot mange in sheep	Worldwide	Sebacil Lösung (Bayer)	Wash, spray	Phoxim
	Horse	Clinical symptoms rare (foot mange)				

Mange, Animals, Table 9 *Psoergates* species and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Psoergates ovis</i>	Sheep	Loss of wool (economic problem)	Australia, New Zealand, South Africa, South America	Sebacil Lösung (Bayer)	Wash, spray	Phoxim

Mange, Animals, Table 10 *Pneumonyssinus* species and control measurements

Parasite	Host	Symptoms	Country	Therapy		
				Products	Application	Compounds
<i>Pneumonyssoides caninum</i> (Nasal mite)	Dog	Chronic sneezing, epistaxis	Worldwide	Intercepton (Novartis)	Oral	Milbemycin, Oxime

Pneumonyssoidic Mange

See Table 10.

intrauterine growth restriction (Scholl and Hediger 1994; Verhoeff et al. 2001).

Mange, Man

Skin disease in animals caused by digging ► [mites](#) such as ► *Sarcoptes* spp. which make funnels in the epidermis that becomes inflamed due to secondary bacterial invasion (► [Acariosis, Animals](#), ► [Scabies](#)).

Congenital Malaria
